The viscosity at 20 °C and a solids content of 75 % is ca. 2000 mPa · s for hydrogenated glucose/corn syrups and 1500 mPa · s for hydrogenated high-maltose syrups.

At pH 5 – 7, maltitol-containing syrups are thermostable up to 200 °C. At lower pH and > 50 °C, however, marked hydrolysis occurs. In the acid or enzymatic hydrolysis of oligosaccharide alcohols, glucose molecules are eliminated preferentially until a molecule of maltitol remains. Maltitol is more difficult to hydrolyze [259].

For these reasons, the nutrition properties of these syrups, such as noncariogenicity [260], suitability for diabetics [261], and reduced calorific value, depend greatly on the composition.

7.2. Maltitol

For the production of maltitol, high-maltose glucose corn syrups are the starting material from which pure maltose is obtained by chromatographic separation on ion-exchange resins (→ Ion Exchangers). Depending on the separation technique, maltose of varying purity (85 – 98 %) is obtained. The syrups are evaporated to a solids content of 50 % and then hydrogenated [262]. Initially, hydrogenated syrups were spray-dried together with a carrier (alginates, methyl celluloses) [263]. The products have a maltitol content of > 85 % and are very hygroscopic.

Crystallization of maltitol from water was achieved in the early 1980s [264], [265]. Continuous crystallization processes are also being used now [266].

Commercially available crystalline maltitol has the following specifications:

Appearance	white powder
Taste	sweet
Odor	neutral
H_2O content	1 % (max.)
Maltitol content (solids based)	≥ 98 %
D-Sorbitol content (solids based)	0.5 % (max.)
Maltotriitol content (solids based)	1.5 % (max.)
Reducing sugar as glucose %	0.1 % (max.)
mp, °C	ca. 147 °C
Sulfate ash content	0.1 % (max.)
Chloride content	50 mg/kg (max.)
Nickel content	1 mg/kg (max.)

KARRER and BÜCHI [267] and WOLFROM and GARDNER [268] were the first to obtain maltitol in the crystalline state from ethanolic solutions.

Physical and Chemical Properties. Maltitol [*585-88-6*], 4-*O*-α-D-glucopyranosyl-D-sorbitol 4-*O*-α-D-glucopyranosyl-D-glucitol), $C_{12}H_{24}O_{12}$, M_r 344.32, *mp* 146 – 147 °C, optical rotation $[\alpha]_D^{20} = +106.5°$. Maltitol forms orthorhombic crystals [264]. It is weakly hygroscopic in the solid state. The *viscosity* of aqueous maltitol solutions corresponds to that of sucrose solutions (→ Sugar, Chap. 4.). For further physical and chemical parameters, see [269].

In the pH range 5 – 7, maltitol and maltitol solutions are stable up to ca. 150 °C. Lower pH values, temperature > 50 °C, and longer contact times result in cleavage of the disaccharide bond [259].

Maltitol is also cleaved by enzyme systems (e.g., of the mucosa). The published values for the Michaelis constant (K_m) and the maximum reaction rate (V_{max}) differ tremendously, probably because individual researchers have worked with substrates of varying purity [270].

Sensory Properties. The relative sweetness of maltitol is generally given as 0.65 [271], although values up to 0.9 are encountered in chocolates [272]. For the enthalpy of solution, see Table 2, Chapter 1.

Physiological Properties. The general comments in Chapter 1 apply to maltitol. Review

articles deal specifically with maltitol and describe its noncariogenicity [273], suitability for diabetics [274], absorption [275], and tolerance and reduced calorific value [276].

Uses. The applications of maltitol correspond largely to those of sugar. However, its hygroscopicity and capacity for browning or flavor development differ. Maltitol can be used in the production of chocolates [272], hard and soft caramel [277], toffees, gummy bears, chewing gum, jams, ice cream, etc. A general review of uses is given in [278].

7.3. Economic Aspects

Maltitol is produced by Roquette (France), Cerestar (Federal Republic of Germany), Cultor-Kotka (Finland), and Hayashibara (Japan).

8. Erythritol

Osmophilic yeasts (e.g., *Moniliella pollinis*) can form erythritol in ca. 50 % yield from carbohydrates [279] or alkanes [280] as substrate. Arabitol, ribitol, and glycerol are formed as byproducts. The companies Nikken Chemicals [281] in Japan and Cerestar [282], [283] in Europe are working on the production and use of erythritol in the food industry.

Chemical and Physical Properties. Erythritol [*149-32-6*] has a M_r 122 and *mp* 126 °C. Its solubility in water at 20 °C is 37 wt % (58 g/100 g water); the enthalpy of solution in water is + 79.4 kJ/kg. The very high enthalpy of solution characterizes the taste profile of this substance.

With regard to nutritional physiology, an important difference between erythritol and other polyols is that erythritol is absorbed in the small intestine to a great extent and excreted unchanged via the kidneys [285]. The excreted portion in humans is ca. 80 % of the amount consumed (for a consumption of 25 g) [286].

Because of its high excretion rate via the kidneys, the physiological calorific value of erythritol is said to be ca. 10 % that of sucrose (i.e., 0.4 kcal/kg = 1.7 kJ/g). Erythritol is also suitable for diabetics [287] and is noncariogenic [288].

1. Introduction

Sulfamic acid (IUPAC recommendation: amidosulfuric acid) has the formula NH_2SO_3H.

Sulfamic acid is a crystalline, strong inorganic acid. It has been produced industrially for ca. 50 years. In expectation of good sales, production plants were set up in a number of industrial countries during the 1950s to 1980s. However, as a result of a decrease in demand, production difficulties, and problems with the disposal of byproducts, all the plants in Europe and the United States have been closed down. Plants are still operating in Japan (Nissan) and Taiwan (several producers).

Table 1. Solubility of sulfamic acid in water

Temperature, °C	Solubility, g/100 g	Concentration, wt %
0	14.7	12.8
10	18.5	15.6
20	21.3	17.5
30	26.1	20.7
40	29.5	22.8
50	32.8	24.7
60	37.1	27.0
70	41.9	29.5
80	47.0	32.0

2. Physical Properties

Pure sulfamic acid is a white, odorless, crystalline, nonhygroscopic compound. It is not volatile at room temperature. Some important data are given in [1], [2].

Density, 25 °C	2.126 g/cm^3
Specific heat	1.1467 J/g
Melting point	205 °C
Vapor pressure	
20 °C	0.8 Pa
100 °C	0.25 Pa
Dissociation constant	1.10×10^{-1}

Sulfamic acid is strongly dissociated in aqueous solution. The pH of a 1 % solution is 1.18. The variation in water solubility with temperature is shown in Table 1. The solubility in water can be increased by the addition of other acids or salts. Sulfamic acid is only sparingly soluble in concentrated inorganic acids, and most organic solvents.

3. Chemical Properties

Sulfamic acid decomposes on heating above 209 °C. Sulfur trioxide, sulfur dioxide, water, ammonia, and nitrogen have been detected as decomposition products [3].

Aqueous solutions of sulfamic acid hydrolyze to ammonium hydrogen sulfate:

$$NH_2SO_3H + H_2O \longrightarrow NH_4HSO_4$$

The rate of hydrolysis depends on concentration, pH, and temperature. Dilute, aqueous sulfamic acid solutions are stable at room temperature. A 10 % solution is 50 % hydrolyzed at 80 °C in 10 h [4].

Chlorine, bromine, and chlorates oxidize sulfamic acid to sulfuric acid:

$$2NH_2SO_3H + KClO_3 \longrightarrow 2H_2SO_4 + N_2 + KCl + H_2O$$

Concentrated nitric acid reacts to give dinitrogen oxide on warming:

$$NH_2SO_3H + HNO_3 \longrightarrow H_2SO_4 + N_2O + H_2O$$

Nitrous acid converts sulfamic acid completely to nitrogen and sulfuric acid, so this reaction can be used for quantitative analysis:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a25_439

$$NH_2SO_3H + HNO_2 \longrightarrow H_2SO_4 + H_2O + N_2$$

Reaction with thionyl chloride forms sulfamyl chloride:

$$NH_2SO_3H + SOCl_2 \longrightarrow ClSO_2NH_2 + SO_2 + HCl$$

Metal hydroxides, oxides, and carbonates are dissolved by sulfamic acid.

The reactions of sulfamic acid with organic compounds have been described in detail [5]. Sulfamic acid reacts with primary and secondary alcohols to alkylammonium sulfates:

$$ROH + NH_2SO_3H \longrightarrow ROSO_2ONH_4$$

Secondary alcohols react only in the presence of amines, which act as catalysts. Tertiary alcohols do not react. Aromatic alcohols, such as phenol, give sulfonates with sulfamic acid, phenylammonium sulfate being an intermediate:

$$C_6H_5OH + NH_2SO_3H \longrightarrow C_6H_5OSO_2ONH_4$$
$$\longrightarrow HO - C_6H_4 - SO_2 - ONH_4$$

Aldehydes form addition products with salts of sulfamic acid. Aromatics with unsaturated side-chains, e.g., styrene, are sulfonated by sulfamic acid, with retention of the side-chain double bond:

$$C_6H_5CH{=}CH_2 + NH_2SO_3H$$
$$\longrightarrow C_6H_5 - CH = CH - SO_2ONH_4$$

4. Production

Sulfamic acid is now produced solely by the urea process; the plants using ammonia and sulfur trioxide [6] have been closed down.

Following a suggestion by BAUMGARTEN, equimolar quantities of urea, sulfur trioxide, and sulfuric acid are reacted directly to sulfamic acid [7]:

$$NH_2CONH_2 + SO_3 + H_2SO_4 \longrightarrow 2NH_2SO_3H + CO_2$$

This is a strongly exothermic reaction. The process is carried out in two stages, based on the following reactions:

$$NH_2CONH_2 + SO_3 \longrightarrow NH_2CONHSO_3H$$

$$NH_2CONHSO_3H + H_2SO_4 \longrightarrow 2NH_2SO_3H + CO_2$$

Urea is stirred in excess sulfuric acid and sulfur trioxide in the first stage. The temperature should be kept below 40 °C to hinder the formation of carbon dioxide. In the second stage, the reaction product from the first stage reacts to form sulfamic acid and carbon dioxide at 50 – 80 °C in the presence of excess sulfur trioxide. After removal of the excess sulfur trioxide, sulfamic acid of purity > 95 % can be obtained [8]. High-purity sulfamic acid is obtained by recrystallization.

According to a Nissan patent, sulfamic acid is produced by the reaction of urea and oleum ($xH_2SO_4 \cdot ySO_3$). The reaction product is recrystallized wet, and the crystallized acid is separated and dried. By grinding under high pressure, preferably 600 – 1500 kg/m^2, a fine crystalline product with average particle diameter $\leq 500\,\mu m$ is obtained [9].

5. Uses

The 1995 world production capacity was ca. 96 000 metrictons [10]. Most of this is used in cyclamate production (→ Sweeteners). The use of sulfamic acid in cleaning agents for carbonate- and phosphate-containing deposits, e.g., boiler scale, is based on its ability to form readily soluble salts and its relatively low corrosive effect on metals. Sulfamic acid is widely used for cleaning machines and instruments in the paper, sugar, dairy, and brewing industries, and for removing deposits in evaporation plants, heat exchangers, and cooling systems.

In some countries, a process involving the treatment of fatty or ethoxylated alcohols with sulfamic acid to produce raw materials for waxes is used on an industrial scale [11].

6. Toxicology

Sulfamic acid is not specifically toxic, and its physiological properties are typical of a strong mineral acid. Sulfamic acid dust has an irritant

effect on the mucous membranes of the nose and pharynx, and the conjuctiva of the eyes. Oral administration of 1.6 g/kg to rats is lethal.

7. Sulfamates

The solubility of the alkaline-earth sulfamates is important for the utilization of sulfamic acid in industry [12].

Ammonium sulfamate can be obtained by neutralization of sulfamic acid with ammonia. Technical grade ammonium sulfamate was formerly produced by reaction of ammonia with sulfur trioxide under pressure.

Ammonium sulfamate is an effective softener for paper. Impregnated paper is not readily flammable [13]. Ammonium sulfamate has also been used for the removal of lime salts without leaving a residue, which would interfere with the tanning process in leather production.

1. Introduction

Sulfur – sulfur bonds occur in numerous inorganic, organic, and biologically interesting compounds. One reason for this is the high bond energy of the S – S single bond (265 kJ/mol). This is the third strongest single bond, after H_2 (435 kJ/mol) and the C – C single bond (330 kJ/mol) [1].

Of the compounds of sulfur with metals, only the alkali and alkaline earth sulfides, which contain the S^{2-} ion [2], and the corresponding hydrogensulfide, are soluble in water. The sulfides of the alkali and alkaline earth metals undergo addition of sulfur with conversion to polysulfides, which can also be regarded as salts of the sulfanes [3].

2. Physical and Chemical Properties of Compounds of the System Na_2S-S

2.1. Physical Properties

The Na_2S-S phase diagram has been widely investigated [4–6], [7], [8] with essentially consistent results being obtained [9]. Above 285°C the phase diagram (Fig. 1) contains two liquid regions: a sodium-rich, single-phase region in which the composition moves continuously towards Na_2S_5 as the sulfur content increases, and a two-phase region where two immiscible liquids – Na_2S_5 saturated with sulfur, and sulfur saturated with Na_2S_5 – coexist [5], [10]. In the sodium-rich part of the diagram, the liquidus curve between Na_2S_2 and Na_2S_4 shows an eutectic, which lies at 235°C according [5], and at 240 ± 2°C according to [11]. According to [5], the eutectic corresponds to the composition Na_2S_3; earlier investigations indicated the composition $Na_2S_{3.24}$. X-Ray diffraction experiments have shown that Na_2S_3 does not exist as a defined polysulfide in the solid state [12]. The solid product with the stoichiometric composition Na_2S_3 contains only Na_2S_2 and Na_2S_4 [13].

Although the above results show that solid sodium trisulfide is unstable, the situation is different for the molten state [14]. A melt with the composition Na_2S_3 consists of a mixture of Na_2S_3, Na_2S_2, and Na_2S_4 [14]. In spite of the undoubted presence of the S_3^{2-} ion in K_2S_3, BaS_3, etc., Raman spectroscopy shows that in molten Na_2S_3 the ion disproportionates into S_2^{2-} and S_4^{2-} ions [15]. Thus, the compositions of the known alkali polysulfides are as listed below [8]:

Li_2S	Li_2S_2				
Na_2S	α-, β-Na_2S_2		Na_2S_4	Na_2S_5	
K_2S	K_2S_2	K_2S_3	K_2S_4	K_2S_5	K_2S_6
Rb_2S	Rb_2S_2	Rb_2S_3	Rb_2S_4	Rb_2S_5	Rb_2S_6
Cs_2S	Cs_2S_2	Cs_2S_3	Cs_2S_4	Cs_2S_5	Cs_2S_6

Figure 1. Phase diagram of the Na – S system between the compositions Na_2S_2 and 100 % S [7]

The following route to Na_2S_3 has been proposed on the basis of the differing solubilities of NaCl and KCl in liquid ammonia (NaCl: 3.02 g/100 g solution; KCl: 0.04 g/100 g solution) [8], [11].

$$2\,NaCl + K_2S_3 \xrightarrow{NH_3} Na_2S_3 + 2\,KCl$$

The question of whether Na_2S_3 can be synthesized was partially elucidated when it was shown that the compound can exist as an ammoniate [11]. X-Ray and thermogravimetric measurements at various temperatures on powdered samples showed that ammonia can be removed at 370 K without fundamentally changing the structure [11]. The eutectoid decomposition reaction is hindered, at least kinetically, at low temperature [11].

Experiments on the melting and crystallization processes in the sodium – sulfur cell show remarkable behavior by some sodium polysulfide compounds [16]. The melting temperatures of, e.g., polycrystalline Na_2S_4 and Na_2S_5 are reproducible for the first melting process, but in subsequent melting and crystallization cycles, the two compounds behave like the products of eutectic composition. With the exception of the disulfide, the polysulfides can form supercooled melts, and vitreous states have been observed. Some data on the melting behavior of polysulfides are given in Table 1 [16].

Sodium monosulfide, Na_2S, like Li_2S, K_2S, Rb_2S, Li_2O, Na_2O, and K_2O, crystallizes with the antifluorite structure, in which each S atom is surrounded by a cube of 8 Na atoms, and each Na atom by a tetrahedron of 4 S atoms [15]. The *mp* is 1170 ± 10°C [17], the heat of fusion $\Delta H_{fus} = 30.1$ kJ/mol [19], the standard entropy $S^{\circ}_{298} = 90.3\ J\,K^{-1}\,mol^{-1}$ [17], and the heat of formation $\Delta H_{298} = -386.6$ kJ/mol, based on [18] [19].

Sodium disulfide crystallizes in two modifications [12]. The transformation from the α- to the β-modification takes place in the temperature range 150 – 250°C [12]. The change in structure is irreversible. Products that solidify from the melt or are tempered at high temperature have the β-structure, which is isotypical with that of Li_2O_2 [20]. Sodium disulfide isolated from alcoholic solution exists in the α-modification, isotypical with the structure of Na_2O_2 [20]. The sodium disulfide was prepared in alcoholic solution by the method proposed in [21] in which an alcoholic solution of sodium tetrasulfide is reduced with sodium metal [12].

The specific heat capacity c_p of α-Na_2S_2 was found to be constant at $1071\ J\,kg^{-1}\,K^{-1}$ over the temperature range 97 – 167°C [16].

For β-Na_2S_2 in the range 191 – 267°C, c_p is $1113\ J\,kg^{-1}\,K^{-1}$ [16]. The relative density d_{20} of α-Na_2S_2 is 2.01, and that of β-Na_2S_2, 2.05. The color of Na_2S_2 is yellow to orange.

Sodium Tetrasulfide. The crystal structure of Na_2S_4 is described in [22]. The structure of the S_4^{2-} ions in sodium tetrasulfide is shown in Figure 2 [23].

The interatomic distance *d* of the sulfur atoms is 207 pm, the valency angle α is 109.8°, and the torsion angle τ is 98° [23].

According to [23], reliable IR and Raman spectra of sodium tetrasulfide were first published in [24], the Na_2S_4 spectra available until then having been falsified by the presence of lines due to the pentasulfide. The relative density of sodium tetrasulfide is $d_{20} = 2.08$ [12].

Figure 2. Structural principle of the ions S_4^{2-}, S_5^{2-}, and S_6^{2-} [23]
In S_4^{2-}, atoms 5 and 6 or 5′ and 6′ are absent, and in S_5^{2-}, atom 6 or 6′ is missing. In gg′-S_5^{2-}, the fifth atom is in position 5. Likewise, the last atom of ggg′-S_6^{2-} would be in position 6′.

Sodium Pentasulfide. Like Na_2S_2 and Na_2S_4, Na_2S_5 in the solid state forms a structure that appears uniform by X-ray diffraction, and is therefore a true chemical compound with a definite chain length [12], [25]. The structure, shown in Figure 2 as gg′−S_5^{2-}, is based on the Raman spectrum of Na_2S_5 [23]. The relative density of Na_2S_5 is $d_{20} = 2.08$ [12].

Some physical properties of anhydrous alkali metal sulfides are listed in Table 2 [26].

Molten Sodium Polysulfide. Conductivity data for some molten sodium polysulfides are plotted in Figure 3 [27]. The values are in the range expected for ionic liquids.

Figure 3. Equivalent conductivity plotted against wt % sulfur for fused sodium polysulfides [27]
a) 420°C; b) 380°C, c) 340°C; d) 300°C; e) 260°C; f) 220°C

At 340°C, the conductivity κ of Na_2S_4 is $0.45\,\Omega^{-1}\,\mathrm{cm}^{-1}$, which compares with

1.11 Ω^{-1} cm^{-1} for $NaNO_3$ and 0.87 Ω^{-1} cm^{-1} for NaSCN at the same temperature.

The conductivity increases with decreasing sulfur content approximately twofold from Na_2S_5 to Na_2S_3. This is partly a result of the increasing ionic concentration as the proportion of sulfur decreases.

The conductivity of pure molten sulfur and of molten sulfur saturated with Na_2S_5 is shown in Figure 4. The two "types of sulfur" show only small differences in their conductivities, in contrast to the conductivity of molten Na_2S_5. This shows that the solubility of Na_2S_5 in sulfur is extremely low [27].

Density values for some sodium polysulfide melts are listed in Table 3 [28].

Comparing the densities of solid and liquid Na_2S_4 and Na_2S_5 shows that the transformation from solid to liquid is accompanied by a volume increase of ca. 8 – 10 % [28].

Figure 4. Temperature dependence of conductivity for liquid sulfur (a) and sulfur saturated with Na_2S_5 (b), [27]

Table 3. Values of parameters in the equation $\varrho = D + E\,(T - 600)$, describing the density of fused sodium polysulfides [28]

$Na_2S_{4.8}$	77.0	573 – 683	1.876	−7.16

2.2. Chemical Properties

Sodium Monosulfide. The chemical properties of sodium sulfide are described in detail in [29–31]. Anhydrous Na_2S is a white solid that readily reacts with moist air to form sodium sulfite and carbonate. Pure NaHS can be obtained by the action of H_2S on anhydrous Na_2S.

Sodium sulfide is very soluble in water. The concentration of a saturated solution of Na_2S at various temperatures is given below [32]:

g Na_2S/100 cm^3	12.2	16.0	21.3	28.0	33.0	40
T, °C	0	20	40	60	80	90

The relationship between wt % Na_2S y and density x at various temperatures is given by [31]:

$$y = -98.24 + 98.28 \cdot x \text{ at } 20°C$$
$$y = -98.73 + 99.01 \cdot x \text{ at } 30°C$$
$$y = -98.40 + 99.01 \cdot x \text{ at } 40°C$$

Aqueous solutions [32] of sodium sulfide react alkaline due to hydrolysis:

$$Na_2S + H_2O \longrightarrow NaHS + OH^- + Na^+$$

Iron compounds dissolve in hydrolyzed sodium sulfide solutions, forming thio complexes with an intense brown-red color. Iron metal is also attacked by concentrated Na_2S solutions.

Na_2S solutions can dissolve sulfur up to a composition corresponding to Na_2S_5.

Sodium sulfide solutions are oxidized by NaOCl solutions; depending on the concentration of the reactants, the temperature, and the pH, various amounts of sulfur and sulfate are formed [31]. For dilute solutions of approximately constant concentration, the ratio of sulfur to sulfate formed is constant. With a large excess of sulfide, the formation of sulfur increases, and for a large excess of NaOCl, the formation of sulfate increases. Sulfate formation is favored by increased temperature. Maximum sulfate formation is observed at pH 10 [31].

Sodium sulfide is oxidized by the Karl Fischer reagent, presumably by the reaction [31]

$$H_2S + I_2 \rightleftharpoons 2\,HI + S$$

Sodium sulfide is appreciably soluble in the lower alcohols (methanol, ethanol) [32].

Sodium Polysulfides. The chemical properties of the sodium polysulfides are described in detail in [29], [30], [33], [34].

Sulfur dissolves readily in alkali metal sulfide solutions with formation of alkali metal polysulfides [34]. These solutions are strongly alkaline owing to the reaction

$$S^{2-}{}_x + 2\,HOH \longrightarrow H_2S_x + 2\,OH^-$$

The S_8 ring is broken by the thiophilic S^{2-} and SH^- ions in accordance with the equation

leading to the formation of nonasulfide ions which can break down to form shorter chains. At the same time, longer chains are formed from S^{2-} ions (e.g., S_2^{2-}, S_3^{2-}, etc.) which can also undergo degradation. In solutions of alkali polysulfides produced from alkali sulfide and sulfur, these reactions take place in single steps and, therefore, constitute a complex dynamic equilibrium between sulfide ions of various chain lengths. This explains why aqueous solutions of polysulfide ions of definite chain length cannot be obtained by reaction of stoichiometric amounts of sulfur with sulfide. Addition of such solutions to cold hydrochloric acid always gives a mixture of sulfanes [34]. Furthermore, of the alkali metal polysulfides M_2S_n , only the

pentasulfide dissolves without decomposition, dissociating to form S_5^{2-} ions [25]. Higher polysulfides with $n > 5$ also form pentasulfide ions with precipitation of the excess sulfur, while the lower polysulfides ($n < 5$) disproportionate into monosulfide, tetrasulfide, and pentasulfide ions, which are in pH-dependent equilibrium with each other [25], [35]:

$$4\,S_4^{2-} + H_2O \rightleftharpoons OH^- + SH^- + 3\,S_5^{2-}$$

Free polysulfide ions consist of sulfur chains [35]. The sulfur atoms of an S_3^{2-} chain are necessarily coplanar, but for longer chains there are possibilities for isomerism, as shown in Figure 5. Thus, for the structure of the S_4^{2-} ion there are two possibilities (Fig. 5 A and B), for the S_5^{2-} ion there are the possible structures (C) and (D), and for the S_6^{2-} ion, the structure (E) [35]. The equilibrium between the polysulfide ions in aqueous solution also appears to influence the production of polymeric polysulfides, represented by the general equation

Figure 5. Idealized stereochemistry (dihedral angle equal to 90°) for polysulfide ions [35]
A, B) *d*- and 1-S_4^{2-}; C, D) *cis*- and *trans*-S_5^{2-}; E) *trans, trans*-S_6^{2-}

$$n\,\mathrm{Hal{-}R{-}Hal} + n\,Na_2S_x \longrightarrow (-RS_x-)_n + 2n\,\mathrm{NaHal}$$

This is essentially a nucleophilic exchange between the halogen and the polysulfide anion. The exact nature of the polysulfide ions that react with the dihalides is not yet clear. The polymer initially formed on addition of dihalide to aqueous sodium polysulfide contains less sulfur than expected.

The degree of sulfur substitution (sulfur grade) is the average number of sulfur atoms in each repeating unit of the polymer. However, if a polymer with, for example, a sulfur grade of 4, is treated with 1 mol Na_2S_4, the sulfur grade in the polymer decreases to 3.1, while that of the polysulfide solution increases by a corresponding amount [36].

For reactions that must be carried out under anhydrous conditions, anhydrous polysulfide reagents can be prepared according to the following reaction scheme [37]:

$$2\,LiBHEt_3 + 5/8\,S_8 \longrightarrow Li_2S_5 + 2\,BEt_3 + H_2$$

$$[Cp_2\,MCl_2] + Li_2S_5 \longrightarrow [Cp_2MS_5] + 2\,LiCl$$

(Cp = cyclopentadienyl; M = Ti, Zr, Hf, V)
The so-called Super-Hydride method has been found to be very versatile for the preparation of polysulfide complexes of transition metals [37].

3. Production of Compounds of the System $Na_2S - S$

Sodium tetrasulfide is nowadays produced from the elements in the absence of water and solvents on an industrial scale; sodium disulfide and sodium monosulfide can be prepared similarly on the laboratory scale [38–42].

A summary of the processes is given in Figure 6. The production of Na_2S_4, Na_2S_2, and Na_2S is briefly described below.

Figure 6. Some production routes to anhydrous, solvent-free sodium monosulfide and polysulfides

3.1. Sodium Tetrasulfide

Sodium tetrasulfide is now produced on an industrial scale in high purity from the elements in the absence of water and solvents.

Molten polysulfide is charged into a cylindrical reactor, with no added water or solvent [38]. Molten sodium and sulfur are added alternately and are mixed with the melt by vigorous agitation. The heat of reaction is removed by a heat-transfer oil in contact with the outer wall of the reactor.

For optimum process operation, the temperature of the polysulfide melt should be in the range 340 – 360°C.

As the molten polysulfide is extremely corrosive, the choice of construction materials is very important. The alloy AlMg appears to be sufficiently resistant. The atmosphere in the reactor is inerted with argon [38].

The preparation of the sodium polysulfides Na_2S_3, Na_2S_4, and Na_2S_5 on the laboratory scale by synthesis from the elements is described in [13]. An equimolar amount of sulfur is added to molten sodium in small amounts with agitation. The reaction product, consisting mainly of Na_2S_2, is cooled, size reduced, and then mixed at room temperature with the required amount of sulfur. The mixture is then melted. Unreacted sodium recovered from the size-reduced reaction product is then added to this polysulfide melt [13].

In another laboratory method, based on early work [5], [21], Na_2S_4 was prepared in alcoholic solution from sodium, hydrogen sulfide, and sulfur [12]. In a widely cited preparation of sodium tetrasulfide or polysulfides from Na_2S and sulfur, alkali metal sulfide, prepared by the reduction of Na_2SO_4, is added to molten sulfur [43].

3.2. Sodium Disulfide

Sodium disulfide, Na_2S_2, is produced by adding a higher sodium polysulfide and sodium, either simultaneously or alternately, to a polysulfide melt [39]. As the melting point of Na_2S_2 (474°C) is higher than the boiling point of sulfur, it is preferable to use sodium tetrasulfide. Thus, sodium disulfide free of water or solvent can be produced in an easily controlled process. The process has three variations [39]. The whole of the polysulfide can be premelted, and the sodium added to the melt until the desired stoichiometric composition is obtained, or sodium and, for example, Na_2S_4 can be added to the melt either alternately or simultaneously [39].

There are many literature references to other methods of producing sodium disulfide. For example, sodium tetrasulfide can be dissolved in alcohol and then reduced with sodium metal to give sparingly soluble Na_2S_2 [21]. It has not been possible to prove conclusively that the product so obtained, which contains 4 – 6 % alcohol, represents a defined alcoholate [12]. High-purity Na_2S_2 can be produced from the elements in liquid ammonia [12].

Small amounts of sodium polysulfide for the investigation of thermodynamic properties have been prepared by melting together Na_2S and sulfur in a small sealed capsule [16].

Sodium disulfide is produced on an industrial scale from sodium hydroxide solution and sulfur [44], and is used for the production of polysulfide polymers [36] (see Chapter 6).

3.3. Sodium Monosulfide

The most important processes for the production of Na_2S are described in detail in [29–31], [45]. Of these, the reduction of sodium sulfate with carbon is described in detail here.

Sodium sulfide is produced in large quantities by the reaction of anhydrous sodium sulfate with carbon in a process that has been used for decades. The reaction, which is carried out at 700 – 900°C, is represented by the following overall equation [32]:

$$Na_2SO_4 + 2\,C \longrightarrow Na_2S + 2\,CO_2 \quad \Delta H = +203.7\ \text{kJ/mol}$$

At ca. 730°C, the evolution of CO_2 begins, and the reaction mass becomes very fluid. On further heating, it becomes pasty, and finally solid. This behavior can be explained by means of the sodium sulfate – sodium sulfide phase diagram (Fig. 7) [32].

The process details and the operation of the reactors or furnaces are described in patents [29]. The rotating-hearth furnace (Fig. 8) operates fully continuous. The sulfate – carbon mixture is delivered by a water-cooled screw feeder (a), onto the outer part of the rotating hearth (b) [32]. As the hearth rotates, a second screw feeder (c) moves the mixture nearer to the center of the plate where the melt passes through the discharge shaft (d).

Figure 7. Phase diagram of the system $Na_2SO_4 - Na_2S$ [30]

Figure 8. Rotating-hearth furnace [32]
a) Screw feeder; b) Rotating hearth; c) Transporting screw feeder; d) Discharge shaft; e) Burner

To ensure sufficient heat transfer to the reaction mixture, the temperature in the gas space of the furnace must be ca. 1100 °C. The furnace lining is strongly attacked by Na_2S.

The sodium monosulfide so produced contains excess carbon, ash components, Na_2CO_3, $Na_2S_2O_3$, and Na_2SO_3. The product is leached with water, and the undissolved components are removed by filtration. The solution is concentrated by evaporation to 60 – 62 % Na_2S. The concentrated solution, which solidifies at ca. 90°C, is converted to the solid form by cooling on rolls or in pans [32]. Depending on process conditions, the purity of the sodium monosulfide obtained can vary between 50 and 98 wt % [29]. The product can be purified in various ways, e.g., by removal of the strongly colored iron compounds from the sodium sulfide solution [46].

High-purity sodium monosulfide can be obtained by treating the reaction product with methanol to dissolve the sulfide, instead of water [47]. Unlike its hydrates, anhydrous sodium sulfide is very soluble in alcohols. The solubility of Na_2S in methanol is 160 g/L at 20 °C, whereas that of $Na_2S \cdot 9\,H_2O$ in methanol is only 30 g/L [47]. Other aliphatic, aromatic, and polyhydroxy alcohols can also be used as extractants: the solubility of Na_2S in ethanol is 90 g/L, and in ethylene glycol >200 g/L. The sodium sulfide obtained by evaporating the extractant is free of water, iron, sulfite, sulfate, and thiosulfate [47].

Sodium sulfide can also be obtained by reducing Na_2SO_4 with hydrogen (Sulfigran process) [32], methane, or other hydrocarbons [29], [32], [45].

The reduction of sodium polysulfides with sodium amalgam to give high-purity monosulfide proceeds according to the following equation [32]:

$$Na_2S + 3\,S \longrightarrow Na_2S_4$$

$$Na_2S_4 + 6\,NaHg_x \longrightarrow 4\,Na_2S + 6\,Hg_x$$

Anhydrous sodium monosulfide is obtained from moist, anhydrous sodium sulfide in a two-stage process [48].

Pure Na_2S can be prepared on a laboratory scale from the elements using liquid ammonia as solvent [12] or without the use of solvents [40–42]. Na_2S has been prepared in the laboratory in two steps:

In the first step, one of three processes was carried out in a preheated kneading machine:

1) Solid Na_2S_4 was charged into the machine and ground. Liquid sodium was then slowly added, maintaining the temperature of the reaction mixture at 120 – 250 °C by means of a heat-transfer oil [40]; or
2) Liquid sodium was charged into the machine, and solid sulfur was slowly added, maintaining the temperature of the reaction mixture at 120 – 250 °C by means of a heat-transfer oil [41]; or
3) Sulfur and sodium were added alternately to powdered sodium monosulfide, prepared by method 1 or 2, maintaining the temperature of the reaction mixture at 120 – 250 °C by means of a heat-transfer oil [42].

All of these first stages gave a blue-black powder as intermediate product.

In the second stage, the intermediate product was placed in a small reactor. The unreacted

residues of sodium and sulfur in the black intermediate product were then allowed to react at 250 – 480 °C. A white sodium monosulfide was produced from all three products of the first stage. The purity of the Na_2S so obtained was consistently >95 wt % [40–42].

4. Sodium Hydrogensulfide [32]

Sodium hydrogensulfide, NaHS, M_r 56.07, *mp* 350 °C, *d* 1.79, is a colorless to yellow solid. The anhydrous salt (95 – 98 % NaHS) is of minor importance. In industry, the following low-iron hydrated products are used [45]:

1) Sodium hydrogensulfide solution (30 % NaHS)
2) Sodium hydrogensulfide flakes (70 % NaHS)
3) Sodium hydrogensulfide powder (95 % NaHS)

4.1. Properties [32]

Sodium hydrogensulfide is very soluble in water [31]. The variation of solubility with temperature is shown below:

g NaHS/100 cm^3	41	50	55	60	65	72
T, °C	5	22	35	39	43	65

Sodium hydrogensulfide forms two hydrates, $NaHS \cdot 2\,H_2O$ and $NaHS \cdot 3\,H_2O$. The aqueous solution has an alkaline reaction.

The solid products are strongly hygroscopic, and are oxidized by atmospheric oxygen.

4.2. Production [32]

Sodium hydrogensulfide is usually obtained by the action of hydrogen sulfide on sodium sulfide or sodium hydroxide solution. If hydrogen sulfide is passed over anhydrous high-percentage sodium sulfide at ca. 300 °C, high-percentage sodium hydrogensulfide is obtained [49]. According to a patent, anhydrous sodium hydrogensulfide is obtained by the reaction of sodium metal with hydrogen sulfide in inert organic solvents [50], and high-percentage solid products can be obtained by the evaporation of aqueous solutions [51].

Hydrated products are obtained by reacting hydrogensulfide with solutions of sodium sulfide or sodium hydroxide (e.g., in spray towers). If sodium hydroxide solution is used, it should be noted that the sodium sulfide formed as an intermediate is less soluble than the end product. Problems arising from this can be avoided by a patented method [52]. Another patent [53] describes how the difference between the solubilities of sodium sulfide and sodium hydrogensulfide can be exploited by allowing hydrogen sulfide to react with sodium sulfide (60 % Na_2S) in lump form in a tower, controlling the temperature so that the sodium hydrogensulfide runs off, leaving behind the sodium sulfide as a solid.

The hot solutions obtained using pure hydrogen sulfide can be converted to solid products by cooling without intermediate treatment. If the hydrogen sulfide contains carbon dioxide, Na_2CO_3 is formed in the solutions in addition to NaHS. A process for obtaining pure products from such solutions is described in a patent [54]. Another patent describes how NaHS solutions can be produced from H_2S-containing gaseous byproducts of petroleum refining [55].

5. Sulfanes

Hydrogen polysulfides, H_2S_n, were named sulfanes by Fehér and Laue in analogy to the alkanes [56].

Present-day knowledge of this extensive class of compounds is mainly due to the work of F. Fehér et al. in the 1950's [57].

5.1. Properties

The sulfanes, H_2S_n, formally constitute the simplest class of polymers of sulfur with other atoms [33].

These unbranched sulfur chains, terminated by hydrogen atoms, are the starting compounds not only for the metallic polysulfides, but also for many covalent compounds containing sulfur – sulfur bonds, including commercial products of the Thiokol type, sulfane sulfonic acids, and sulfur-vulcanized rubber. The various polymers that contain sulfur chains have in

common that they react as electrophiles towards thiophiles [33], [58].

The sulfanes H_2S_n with $n = 2-8$ have been prepared and isolated in pure form. Accurate determination of chain length distribution in sulfane mixtures and detection of higher sulfanes (up to H_2S_{35}) first became possible with the use of NMR spectroscopy on sulfanes dissolved in benzene or benzene/CS_2 [56]. All sulfanes consist of unbranched chains of sulfur atoms, reflecting the well-known chain-forming tendency of the element. The sulfanes are reactive liquids whose densities, viscosities, and boiling points increase with increasing chain length. H_2S_2, which is an analog of H_2O_2, is colorless. The higher homologues have a yellow color which becomes more intense with increasing chain length [15].

Physical Properties [32]. Some physical and thermodynamic data are given in Table 4. More detailed information can be found in [59]. Extensive spectroscopic experiments and calculations to elucidate the structures of disulfane and trisulfane can be found in [60–62].

Chemical Properties. The sulfanes are soluble in hydrogen sulfide, benzene, and chloroform [30]. All sulfanes are vigorously decomposed by solutions of alkalis.

The sulfanes are readily oxidized. They are thermodynamically unstable, i.e., the thermodynamic equilibrium [32]

$$xH_2S_n \rightleftharpoons xH_2S + 1/8[x(n-1)]S_8$$

lies mainly to the right-hand side. Also, traces of alkali that dissolve from the surface of glass vessels can cause decomposition (i.e., sulfur precipitation, in accordance with the above equation) [15], [34].

Sulfanes dissolve rapidly and without decomposition at 120°C in molten sulfur [32]. At higher temperature, these solutions decompose, liberating H_2S. If NH_3 in the ppm range is added as a catalyst, this decomposition to H_2S and S becomes explosive. This is utilized in the Claus process for producing sulfur, to prevent a slow outgassing of the H_2S.

The decomposition to H_2S and S takes place even on slight heating. It proceeds more rapidly as the temperature increases (up to 100 °C) and is strongly accelerated by light, especially sunlight and UV light [32].

The reaction of sulfanes with reactive alkenes is described in [63]. The addition of a mixture of sulfanes H_2S_n to 2,3-dimethyl-1,3-butadiene is an exothermic reaction which proceeds readily at room temperature in nonpolar solvents:

If the unsaturated compound contains two reactive double bonds, sulfane addition can be used to prepare sulfur-rich polymers [63].

Sulfanes react quantitatively with excess sulfite to form hydrogen sulfide and thiosulfate [15], [33]:

$$H_2S_x + (x-1)SO_3^{2-} \longrightarrow H_2S + (x-1)S_2O_3^{2-}$$

This reaction provides a useful method of quantitative analysis by determining the H_2S formed by precipitation as CdS, and the thiosulfate by iodometry.

The reaction with CN^- ions proceeds analogously:

$$H_2S_n + (n-1)CN^- \longrightarrow H_2S + (n-1)\,SCN^-$$

The thiocyanate formed can be determined colorimetrically as $Fe(SCN)_3$ [15], [33].

1,3-Diketones in organic solvents saturated with HCl react with sulfanes to form 1,2-dithiolium ions [34], [64].

Sulfanes have been reacted with chlorosulfanes to obtain novel sulfur rings [65], [66]. Some examples are given below [66]:

$$H_2S_6 + S_4Cl_2 \longrightarrow S_{10} + 2\,HCl$$

$$H_2S_4 + S_2Cl_2 \longrightarrow S_6(50\,\%) + S_{12}(3\,\%) + 2\,HCl$$

$$H_2S_8 + S_4Cl_2 \longrightarrow S_{12}(18\,\%) + 2\,HCl$$

$$H_2S_8 + S_{10}Cl_2 \longrightarrow S_{18} + 2\,HCl$$

$$H_2S_{10} + S_{10}Cl_2 \longrightarrow S_{20} + 2\,HCl$$

Table 4. Physical and thermodynamic data for sulfanes

Sulfane	d_{20}	n_D^{20}	p^{25}, mbar	S^{25}, J/K	$C^{25}{}_{p,l}$, J mol^{-1} K^{-1}	$C^{25}{}_{p,s}$, J mol^{-1} K^{-1}
H_2S_2	1.334	1.631	149.226	165	92.528	51.078
H_2S_3	1.499	1.729	2.5935	216	123.510	74.525
H_2S_4	1.582	1.791	0.06783	264	154.074	97.971
H_2S_5	1.644	1.836	0.002527	351	184.638	120.998
H_2S_6	1.688	1.867				
H_2S_7	1.721	1.893				
H_2S_8	1.747	1.912				

5.2. Production

If aqueous solutions of alkali metal polysulfides are added to excess concentrated hydrochloric acid with cooling, and local alkalinity due to the hydrolysis of Na_2S_n is avoided, a yellow "crude oil" ($H_2S_4, H_2S_5, H_2S_6, H_2S_7, H_2S_8$) separates. This can be separated into its pure components by high-vacuum distillation or selective extraction. The lower sulfanes H_2S_2 and H_2S_3 can be obtained by distillation with cracking [34], [67], [68]. As even trace amounts of alkali on the surface of glass catalyze the decomposition of sulfanes to H_2S and S, great care is necessary in this process. Glass apparatus intended for use with sulfanes must be pretreated with gaseous HCl [59]. Because of the low thermal stability of the higher sulfanes, these compounds can only be handled at low temperature [69].

The crude oil, containing a mixture of sulfanes, can be produced from various starting materials [59]:

1) From aqueous polysulfide solutions
2) From anhydrous polysulfides
3) From hydrogen sulfide and sulfur
4) By the reaction of lower sulfanes with chlorosulfanes
5) From aqueous solutions of thiosulfate and dithionite
6) By the cathodic reduction of saturated aqueous solutions of SO_2

The third reaction indicates that liquid sulfur produced by the Claus process can contain large quantities of sulfanes [69]. Their formation in the Claus combustion chamber is essentially determined by the equilibrium between sulfur vapor, hydrogen sulfide, and sulfanes.

6. Uses of Sulfides and Sulfanes

Much of the new knowledge of the system Na_2S-S mentioned above has come from research into sodium – sulfur cells. However, the Na_2S_n compounds that are formed and decomposed in these cells are initially produced from the elements sodium and sulfur, so that the batteries that contain these cells have no economic implications for the production and use of anhydrous, solvent-free sodium polysulfide compounds [10], [70].

An established application is in the production of *sulfur dyes* [71], which are produced by the two methods (→ Sulfur Dyes):

1) The polysulfide bake method, where sulfur or sulfur – sodium sulfide is heated in the dry state with aromatic amino or nitro compounds or with nitrogen-free organic substances such as cresol, anthracene, or decacyclene
2) The polysulfide melt method, in which organic compounds are refluxed with polysulfide in an aqueous or alcoholic medium

The water-insoluble sulfur dyes are dissolved by reduction to the leuco form, generally with sodium sulfide. The leuco dyes become attached to the fibers, and the sulfur dye is then fixed on the fiber by oxidation with peroxides or perborates [71].

Anhydrous, solvent-free sodium tetrasulfide is extensively used in the production of *organosilanes*, which are used in the rubber industry:

$$2(RO)_3Si-(CH_2)_3-Cl + Na_2S_4 \longrightarrow (RO)_3Si-(CH_2)_3-S_4-(CH_2)_3-Si(OR)_3 + 2\,NaCl$$

The ethyl derivative of bis(trialkoxysilylpropyl) tetrasulfide (Si 69) is one of the most important organofunctionalized silanes [72]. Organosilanes are used in the rubber industry in combination with various fillers to produce elastomers with improved static and dynamic vulcanizate properties [73]. These silanes have two different reactive groups that react with the silanol groups of fillers during compounding in rollers or kneaders, and form chemical bonds to the polymer and cross-linking agents during vulcanization. Si 69 can also be used as a sulfur donor that gives reversion-free vulcanization (equilibrium cure system) [73].

Another example of the use of an anhydrous sulfide is in a process for producing *poly(phenylene sulfide)* [33], [74], [75] (see also → Polymers, High-Temperature, Chap. 5.). In the production of poly(phenylene sulfide), 1,4-dichlorobenzene and sodium sulfide are reacted at ca. 280°C under pressure in a polar aprotic solvent, usually *N*-methyl-2-pyrrolidone [76]. While aliphatic polysulfides can easily be prepared by nucleophilic exchange reactions of chloride with sulfide, the reaction with aromatic compounds is much more difficult because of the considerably lower reactivity of the aromatically bonded chlorine [33]. It has been suggested that formation of poly(phenylene sulfide) does not proceed like a normal polycondensation [77]. The reaction is a one-electron transfer process in which radical cations act as reactive intermediates [77]. Poly(phenylene sulfide) can be used with very high contents (up to 70 %) of fillers such as glass fiber, carbon fiber, or minerals. Its good chemical resistance (PPS is practically insoluble in all the usual solvents) and inherent flame-retardant properties enable it to be used under severe thermal and chemical conditions. Reinforced PPS can replace metals in many applications, e.g., in the construction of machinery and equipment, pump housings, and gear wheels [76].

Sodium sulfide, sodium hydrogensulfide, and sodium polysulfide are sometimes used in the same fields of application [31]. This is also true to some extent of the sulfanes, although their instability prevents their large-scale use [32]. Examples are the manufacture of polysulfide polymers and the sulfide reduction of polynitroaromatics, both described below.

Aliphatic polysulfides of the thiokol type have the general formula $(C_xH_{2x}S_y)_n$. These find wide application [74] as sealants (→ Sealing Materials, Chap. 3.) and, in combination with epoxy resins, as adhesives and mastics. These products have a marked ability to expand and contract, are elastic over a wide temperature range, and are resistant to seawater, solvents, and many chemicals. The best known commercial products are the Thiokols, which are polyalkyl- and polyalkoxypolysulfides. They are produced by the condensation of Na_2S_n with dichloroalkyls and bischloroalkylformals [79], [80]. Trichloroalkanes [81], epichlorohydrin [82], condensation products of α-monochlorohydrin formaldehyde [83], and monochloro alcohols [80] are also used as modifiers in the condensation reaction. The basic properties of these polysulfides mainly depend on the sulfur content [36]. The Na_2S_n compounds can be obtained by the reaction of NaOH with sulfur [44]. At temperatures of <110°C and with NaOH concentrations of <30 wt %, polysulfide and thiosulfate are formed according to the equation

$$10\,S + 6\,NaOH \longrightarrow 2\,Na_2S_4 + Na_2S_2O_3 + 3\,H_2O$$

whereas at higher NaOH concentrations (up to 35 wt %) and higher temperatures (100 – 320°C) sulfite is also formed [44]:

$$6\,NaOH + (2x+1)S \longrightarrow 2\,Na_2S_x + Na_2SO_3 + 3\,H_2O$$

The autoxidation of aqueous polysulfide solutions in the temperature range 23 – 40°C, the kinetics of polysulfide – thiosulfate disproportionation [84], [85], and equilibria of polysulfide ions in solution [86] should be mentioned in this connection [87]. The reaction usually proceeds very rapidly from sulfite to thiosulfate, so that only small amounts of sulfite remain. However, as sulfite crystallizes from concentrated NaOH solution, small amounts of thiosulfate remain in the solution [88].

The polymers produced by the reaction of alkyl chlorides with sodium polysulfide are obtained as high molecular mass, rubber-like products with a very limited range of uses. The polymers can be selectively cleaved by the action of sodium hydrogen sulfide on the disulfide groups, allowing the average chain length to be controlled [89].

$$-R-S-S-R + NaSH \longrightarrow R-SNa + H-S-R + S$$

The sulfur liberated in this reaction reacts with added sodium sulfite to form sodium thiosulfate [89]:

$$Na_2SO_3 + S \longrightarrow Na_2S_2O_3$$

The bis(vinylarylalkyl) polysulfides [90], obtained by reacting 4-vinylbenzyl chloride with Na_2S-S, are used as coatings and sealants in the form of copolymers with halogenated alkanes.

Aromatic amino compounds can be prepared by the reduction of polynitroaromatics with sulfide [91]. Sulfide reductions are carried out in industry with Na_2S, NaHS, Na_2S_2, or ammonium sulfide solutions. The reactions are not exactly stoichiometric, proceeding approximately in accordance with the following equations:

$$4\,Ar-NO_2 + 6\,Na_2S + 7\,H_2O \longrightarrow 4\,Ar-NH_2 + 3\,Na_2S_2O_3 + 6\,NaOH$$

$$4\,Ar-NO_2 + 6\,NaSH + H_2O \longrightarrow 4\,Ar-NH_2 + 3\,Na_2S_2O_3$$

$$Ar-NO_2 + Na_2S_2 + H_2O \longrightarrow Ar-NH_2 + Na_2S_2O_3$$

Some other important products obtained by using the sulfide reaction are 1,2-diamino-4-nitrobenzene from 2,4-dinitroaniline and NaSH; 2-amino-4-nitrophenol from 2,4-dinitrophenol and NaSH; and 4,6-dinitro-2-aminophenol (picraminic acid) from picrinic acid and NaSH [91].

To reduce friction and increase load-bearing capacity, EP (extreme-pressure) and AW (antiwear) *oil additives* are added to engine oils, transmission oils, turbine oils, and machining oils and their emulsions [92], [93]. It is known that sulfur-containing compounds in which the sulfur is in "available" form perform especially well in this application. Especially suitable are those compounds with polysulfide bridges in which the sulfur atoms are in a labile, active form, are liberated at elevated temperature, and can form metal sulfide coatings on the metal surface. These coatings usually have a lower coefficient of friction than the metal itself and thus improve frictional behavior [92], [93].

These sulfur-containing compounds can be prepared by reacting epoxides with an alkali metal disulfide or tetrasulfide [92]:

In accordance with the above reaction scheme, elemental sulfur is liberated when Na_2S_4 is used [92].

Oil additives can also be produced by the reaction of Na_2S or Na_2S_n, often in combination with elemental sulfur, with chlorinated organic compounds. These compounds can be formed by the addition of an S – Cl compound (e.g., S_2Cl_2) to a double bond (e.g., isobutene), and then condensed with Na_2S-S [94–99]. Other products may be obtained from the reaction of aromatic hydroxy compounds (e.g., 2,6-di-*tert*-butylphenol or 2,4,6-tri-*tert*-butylphenol) with aldehydes or ketones and Na_2S [100].

The reaction of 4-chlorotetrahydropyran with Na_2S in a methanol/ethanol mixture, followed by hydrogen peroxide oxidation of the resulting thiol group leads to bis(tetrahydropyranyl)disulfide, which is used as a lubricant additive [101].

Dialkylbenzyl disulfides, which are used as oil additives, are produced from a catalytically cracked naphtha fraction (boiling range 164 – 250 °C), which is chloromethylated with formaldehyde – HCl, and then reacted with Na_2S_2 [102].

In a similar process, benzyl chloride and Na_2S_2 are reacted at 80 – 90 °C for 20 h to produce dibenzyl disulfide, which is used as a component of an oil additive [103].

The production of additives for high-pressure lubricants is described in [104]. A mixture of xylol isomers is chloromethylated and then reacted with Na_2S_3 (a mixture of Na_2S_2 and Na_2S_4) to form a polysulfide.

A group of microcrystalline Al – Na silicates with various sulfur contents have been referred to as ultramarines [105]. Analysis gives an approximate empirical formula of $(Na_8Al_6Si_6O_{24}S_4)_n$, suggesting the name sodium aluminum silicate polysulfide.

The production of an *ultramarine* and a green pigment from zeolites and Na_2S_5 by heating to

>300 °C has been reported [106]. The color of the ultramarines may be due to singly charged polysulfide(−1) radical ions [107], [108].

Sodium monosulfide solutions mixed with $FeSO_4$, $Ca(OH)_2$, and a polymeric flocculating agent are used to remove copper from aqueous solutions, process liquors, and wastewater [109]. Lead can be removed by using a mixture of caustic soda solution, sodium monosulfide solution, and aluminum chloride [110].

7. Safety and Environmental Aspects [111]

Sodium sulfide and Na_2S_n are classified as irritants in GefStoffV [112], as indicated by the hazard symbol C.

The following R and S phrases are applicable:

R31: "Toxic gases produced on contact with acids"
R34: "Causes irritation"
S26: "On contact with eyes, rinse immediately with plenty of water, and seek medical help"
S45: "In case of accident or illness, seek medical help immediately. Show this label if possible."

In accordance with GefStoffV vessels containing Na_2S or Na_2S_n should carry the name of the substance in permanent printed letters, the hazard symbol "irritant", the hazard information R 31 – 34, and the safety advice S 26 – 45 [113], [114].

Aqueous solutions of Na_2S, NaHS, and sodium polysulfides must always be maintained at a pH of >10 to prevent liberation of toxic hydrogen sulfide [3]. The hazardous properties of hydrogen sulfide and its effects on humans are described in [32] (see also → Hydrogen Sulfide, Chap. 10.).

Solid sodium sulfide, sodium hydrogensulfide, and sodium polysulfide form strongly alkaline solutions when dissolved in water, and these can cause severe irritation of the eyes and skin. Goggles must therefore be worn. When working with larger quantities, impermeable protective clothing consisting of rubber boots (not leather-soled shoes) and long rubber gauntlets must also be worn.

If dust is formed, respirators with combination B/P2 type filters (color code: gray with white ring) must be worn [113].

In case of fire, respiratory equipment with an independent air supply must be used, completely sealed chemically-resistant clothing must be worn while fighting the fire, and the auxiliary equipment used must be resistant to caustic solutions [113]. Note that sulfide solutions can emit hydrogen sulfide on heating, which can represent a potential hazard during storage or in production [31].

Industrial safety data for sodium sulfide, sodium polysulfide, and sodium hydrogensulfide are given in [111], [115].

Sulfide is classified as a hazardous substance according to § 7 a of the German Water Management Act [116]. In accordance with the current state of the art of the process in which byproduct sulfide is formed, the sulfide content of wastewater has to be reduced. This can be carried out in various ways, e.g., by oxidation of the alkaline solution with H_2O_2 [117]:

$$Na_2S + 4\,H_2O_2 \longrightarrow Na_2SO_4 + 4\,H_2O$$

The limit values for the sulfide content of wastewater are taken from the Framework Wastewater Directive or a recommendation of the German wastewater technical association (ATV) for indirect dischargers. Some values (in mg/L) are listed below [118]:

Appendices to Framework Wastewater Directive (1992)	
Appendix 25 (leather manufacture, fleece treatment, leather fiber production): wastewater from soaking, liming, and deliming, including washing	2
Appendix 37 (manufacture of inorganic pigments): Source type 1.1.3 (lithopone, zinc sulfide pigment, and precipitated barium sulfate)	1
Appendix 39 (manufacture of nonferrous metals)	1
Appendix 40 (metal working and treatment)	
Source type 1.1.1 (electrolytic)	1
Source type 1.1.2 (pickling)	1
Source type 1.1.4 (burnishing)	1
Source type 1.1.7 (printed circuit manufacture)	1
Source type 1.1.8 (battery manufacture)	1
Source type 1.1.9 (enamelling)	1
Appendix 47 (scrubbing of furnace combustion gases)	0.2
34th Framework Wastewater Directive (manufacture of barium compounds)	1
38th Framework Wastewater Directive (textile manufacture)	0.1
43rd Framework Wastewater Directive (synthetic fibers): Source type 2.1.3 (manufacture of viscose spun fiber)	15
Wastewater technical association (ATV) Information sheet A 115 (yellow printing)	2

8. Economic Aspects [119]

Sodium monosulfide is supplied commercially in the form of flakes containing 60 – 62 % Na_2S.

Major producers of the monosulfide include Tessenderlo Chemie (Belgium) and Foret (Spain). There are also producers in Germany, Italy, and France.

The output of sodium monosulfide in Western Europe is estimated to be 50 000 t/a in the mid 1990s. Excluding the considerable quantities exported to the African copper mines, this consumption is distributed among the following areas of use:

Dehairing agents for the leather industry	40 %
Precipitation of heavy metal ions (chemical industry)	30 %
Production of sulfur dyes	20 %
Other uses	10 %

Sodium hydrogensulfide is supplied in the following forms:

1) In powder form with a purity of 95 %
2) In flake form with a purity of 70 – 74 %
3) As a 30 % solution

Sodium hydrogensulfide is manufactured by the sodium monosulfide producers mentioned above, and also by Goldschmidt, Rhodanid Chemie, and Leuna. The main producers in the United States are Jupiter Chemical, PPG Industries, and Ethyl Corp.

As sodium hydrogensulfide is used in the same areas as Na_2S, no reliable information is available concerning the production and consumption of NaHS in Western Europe. In the United States, about two-thirds of annual production (i.e., ca. 180 000 t/a) is of lower quality (low grade, 20 – 30 % NaHS) and is used in the cotton industry.

For many years, sodium polysulfide has been available only in solution. Sodium polysulfide solution is supplied by Goldschmidt (Germany), Witton (United Kingdom), PPG (United States), and Sankyo Kasei (Japan).

Approximately 25 000 t/a polysulfide solution, produced mainly by Morton International (United States), Toray Thiokol (Japan), and Akcros (Greiz-Dölau, Germany), is used in the production of polysulfide elastomers.

Sodium polysulfides are also available in anhydrous and solvent-free form, but the price of this material is considerably higher than that of the aqueous solution.

9. Transportation [120]

Sodium sulfide with at least 30 % water of crystallization is classified as follows:

RID/ADR	Class 8, no. 45 b
IMDG Code	Class 8, UN no. 1849, PG II
ICAO – TI/IATA – DGR	Class 8, UN no. 1849, PG II

Approved packaging for sodium sulfide has been harmonized for all means of transport. Intermediate bulk containers are permitted for land and sea transport. Portable tanks (rail tank cars, road tank cars, tank containers) are permitted for land and sea transport.

Sodium sulfide with less than 30 % water of crystallization is classified as follows:

RID/ADR	Class 4.2, no. 13 b
IMDG Code	Class 4.2, UN no. 1385, PG II
ICAO – TI/IATA – DGR	Class 4.2, UN no. 1385, PG II

Approved packaging has been harmonized for all means of transport, and must be hermetically sealed. Bags are not permitted for sea transport. Bags may be used for land transport provided they are loaded on palettes and forwarded as full load. Intermediate bulk containers are only permitted for land and sea transport. Portable tanks (rail tank cars, road tank cars, tank containers) are permitted only for land transport.

Sodium hydrogensulfide with at least 25 % water of crystallization is classified as follows:

RID/ADR	Class 8, no. 45 b
IMDG Code	Class 8, UN no. 2949, PG II
ICA – TI/IATA – DGR	Class 8, UN no. 2949, PG II

Packaging has been harmonized for all means of transport. Intermediate bulk containers and portable tanks are permitted for land and sea transport.

Sodium hydrogensulfide with less than 25 % water of crystallization is classified as follows:

RID/ADR	Class 4.2, no. 13 b
IMDG	Class 4.2, UN no. 2318, PG II
ICAO – TI/IATA – DGR	Class 4.2, UN no. 2318, PG II

Packaging has been harmonized for all means of transport, and must be hermetically sealed. Bags are not permitted for sea transport, but can be used for land transport provided they are loaded on palettes and forwarded as full load. Intermediate bulk containers are permitted for land and sea, and portable tanks only for land transport.

Sodium polysulfides are not specifically named in the transport regulations, but should be classified as follows:

RID/ADR	Class 8, no. 45 b
IMDG Code	Class 8, UN no. 1759, PG II (solid) Class 8, UN no. 1760, PG II
ICAO – TI/IATA – DGR	Class 8, UN no. 1759, PG II (solid) Class 8, UN no. 1760, PG II (liquid)

Packaging has been harmonized for all means of transport. Intermediate bulk containers and portable tanks are permitted for land and sea transport, with restrictions for solid polysulfide in portable tanks.

1. Introduction

Sulfinic acids are synthetic chemical building blocks that also occur in living organisms. For example, allicin, *S*-2-propenyl 2-propene-1-sulfinothioate [*539-86-6*] (**1**) is a component of extract of garlic [1]. It can be prepared by oxidation of diallyl disulfide with *m*- chloroperbenzoic acid [2]:

1

Allicin has antibiotic properties [3], and it has also been found to be an effective antithrombotic and an inhibitor of blood platelet aggregation [3,4]. In inflammatory processes (e.g., allergies, asthma, rheumatism, etc.) allicin causes 100 % inhibition of lipoxygenases [5] as well as inhibiting the formation of arachidonic acid [6], which plays an important role in such processes (→ Anti-inflammatory – Antirheumatic Drugs). Animal experiments have shown that cholesterol formation is also significantly lowered by allicin [7]. The biosynthesis of taurine, an important neurotransmitter in living organisms (→ Neuropharmacology, Chap. 5.2.1.), proceeds from cysteine via cysteinesulfinic acid and then hypotaurine [8]. More information in [9].

2. Properties

Physical Properties. Table 1 lists a number of aliphatic and aromatic sulfinic acids together with their CAS registry numbers, melting points, and methods of synthesis.

Chemical Properties. Sulfinic acids are compounds with the following general formula [33,34]:

Sulfur has a coordination number of 3 in these compounds, and is in the +4 oxidation

Table 1. Physical data for sulfinic acids whose methods of synthesis are described in the text (all compounds are colorless in the pure state)

Sulfinic acid	Molecular formula (molecular mass)	CAS registry no.	*mp*, °C	Method of synthesis	Reference
$C_2H_5-SO_2H$	$C_2H_6O_2S$ (94.13)	[*598-59-4*]	liquid	oxidation of ethanethiol with *m*-chloroperbenzoic acid reduction of ethanesulfonyl chloride with zinc cleavage of sulfones with thiolate	[10] [11] [12]
$H_3C-(CH_2)_3-SO_2H$	$C_4H_{10}O_2S$ (122.19)	[*55109-28-9*]	liquid	oxidation of butanethiol with *m*-chloroperbenzoic acid reduction of butanesulfonyl chloride with triethylaluminum cleavage of sulfones with sodium cyanide from butyllithium and sulfur dioxide	[10] [13] [14] [15]
$H_3C-(CH_2)_7-SO_2H$	$C_8H_{18}O_2S$ (178.30)	[*3944-71-6*]	5–8	reduction of octanesulfonyl chloride with triethylaluminum	[13]
$H_3C-(CH)_{11}-SO_2H$	$C_{12}H_{26}O_2S$ (234.40)	[*26535-63-7*]	35–36	from dodecylmagnesium chloride and sulfur dioxide cleavage of sulfones with thiolate	[16] [12]
$HO_2S-(CH_2)_4-SO_2H$	$C_4H_{10}O_4S_2$ (186.25)	[*6340-77-8*]	122–126	reduction of 1,4-butanebis(sulfonyl chloride) with sodium sulfite	[17], [18]
Cl_3C-SO_2H	$CHCl_3O_2S$ (183.44)	[*7430-24-2*]	liquid	reduction of trichloromethanesulfonyl chloride with hydrogen sulfide	[19]
F_3C-SO_2H	CHF_3O_2S (134.08)	[*34642-42-7*]	liquid	reduction of trifluoromethanesulfonic acid with hydrazine reduction of trifluoromethanesulfonic acid with zinc reduction of trifluoromethanesulfonic acid with potassium iodide in acetone	[20] [21] [22]
$4\text{-}CH_3-C_6H_4-SO_2H$	$C_7H_8O_2S$ (156.20)	[*536-57-2*]	84	reduction of 4-toluenesulfonyl chloride with triethylaluminum reduction of 4-toluenesulfonyl chloride with zinc reduction of 4-toluenesulfonyl chloride with lithium aluminum hydride from toluene and sulfur dioxide/aluminum trichloride from the diazonium salt of toluene and sulfur dioxide–copper powder	[13] [23] [24] [25] [26]
$4\text{-}(H_3C-CO-NH)-C_6H_4-SO_2H$	$C_8H_9NO_3S$ (199.23)	[*1126-81-4*]	155	reduction of *p*-acetamidobenzenesulfonyl chloride	[27], [28]
$C_6H_5-CH_2-C_6H_4-4\text{-}SO_2H$	$C_{13}H_{12}O_2S$ (232.30)	[*58661-47-5*]	70–72	intramolecular rearrangement of diarylsulfones with butyllithium	[29]
$H_3C-CO-CH_2-CH_2-SO_2H$	$C_4H_8O_3S$ (136.17)		94–95	cleavage of sulfones with sodium cyanide or thiolate	[30]
	$C_7H_8O_3S_2$ (204.27)	[*65373-90-2*]	91–92	cleavage of sulfones with sodium cyanide or thiolate	[30]
$H_2N-C(NH)-SO_2H$	$CH_4N_2O_2S$ (108.12)	[*1758-73-2*]	144 (decomp.)	oxidation of thiourea with hydrogen peroxide	[31]
$HO-CH_2-SO_2Na$	CH_3NaO_3S (118.08)	[*149-44-0*]	63–64	from formaldehyde and sodium dithionite	[32]

state. Sulfinic acids have an asymmetric, pyramidal structure in which the sulfur atom constitutes a chiral center. Free sulfinic acids are relatively unstable compounds. On storage or heating they tend to disproportionate (via intermediates) with the loss of water to give sulfonic acids and S-esters of thiosulfonic acids [15, 16, 35–38]. Some sulfinic acids decompose as soon as they are formed. For example, benzo-1,3-thiazole-2-sulfinic acid desulfinates immediately upon acidification of the sodium salt, giving benzo-1,3-thiazole (**2**) [39]:

Aromatic sulfinic acids are generally more stable than long-chain aliphatic sulfinic acids, which are in turn more stable than their short-chain counterparts. Sulfinic acids are best stored as the alkali metal salts, from which they can be liberated with mineral acid [40].

Sulfinic acids are somewhat weaker acids than the corresponding sulfonic acids (→ Sulfonic Acids, Aliphatic), with pK_a values between 1.2 (aromatic sulfinic acids) and 2.2 (aliphatic sulfinic acids). Aromatic sulfinic acids generally crystallize readily as colorless compounds that are sparingly soluble in water but readily soluble in diethyl ether. Aliphatic sulfinic acids are often obtained as oily or low-melting compounds that are soluble in many organic solvents. Further information in [41].

3. Preparation of Sulfinic Acids and their Salts

Sulfinic acids can be synthesized by reduction of compounds containing sulfur in the +6 oxidation state, transformation of other sulfur +4 compounds, oxidation of sulfur +2 compounds, and nucleophilic cleavage of sulfone-like species; review in [42].

3.1. Reduction of Sulfonic Acid Derivatives

The preparation of sulfinic acids and their salts by reduction of sulfonic acid derivatives is straightforward, especially from the readily accessible sulfonyl chlorides.

$$R-SO_2Cl + 2e^- \longrightarrow R-SO_2^- + Cl^-$$

Sodium sulfite, zinc, iron, magnesium, and stannous chloride are frequently used as reducing agents [11, 18, 23, 28, 36, 40, 43–45]. The use of lithium aluminum hydride [24], alkylaluminum compounds [13], sodium in liquid ammonia [46], and electrochemical methods [47], has also been investigated. These alternative procedures often lead to high yields, but they have not been adopted on an industrial scale because of technical complications or cost. For additional synthetic information see [48].

Synthesis of 1,4-Butanedisulfinic Acid [17, 18]. A solution of 65.5 g (0.52 mol) anhydrous sodium sulfite in 310 mL of water is mixed with 128 g (0.52 mol) of magnesium sulfate heptahydrate to give a thick precipitate. This mixture is heated to 40–50 °C and 51 g (0.2 mol) of 1,4-butanebis(sulfonyl chloride) is added. The mixture is kept alkaline by the slow addition of ca. 23 g of magnesium oxide. The sulfinic acid precipitates as a magnesium salt. Acidification with dilute sulfuric acid, extraction with diethyl ether, and evaporation gives 1,4-butanedisulfinic acid, *mp* 122–126 °C.

Sodium Ethanesulfinate [11]. 436 g (3.4 mol) of ethanesulfonyl chloride is added dropwise with stirring over 3–4 h to a mixture of 500 mL of water, 500 g of ice, and 340 g (5.2 mol) of zinc dust. The temperature is maintained at +5 °C by continuous addition of 500 g of ice. The reaction mixture is stirred for 1 h and then a solution of 350 g of sodium carbonate decahydrate in 1.5 L of water at 80–90 °C is added over 1.5 h. The reaction mixture should remain distinctly alkaline. It is subsequently filtered, and the residue is washed with warm water. The filtrate and washings are evaporated to give 232 g of the sodium salt, from which the free sulfinic acid can be obtained.

3.2. Sulfination with Sulfur Dioxide

Sulfur dioxide sulfinates both aliphatic and aromatic organometallic compounds, (e.g., Grignard reagents [45], organoaluminums [49]), and particularly organolithiums [50], to give the corresponding sulfinic acid salts:

p-Dodecylbenzenesulfinic Acid [50]. A solution of 29.2 g (0.09 mol) *p*-dodecylbromobenzene in 120 mL of diethyl ether is added dropwise to 1.5 g (0.22 mol) of finely cut lithium. The reaction mixture is stirred under reflux for 1h and then cooled in an ice bath, after which sulfur dioxide is passed through the cooled solution for ca. 30 min. A further 100 mL of diethyl ether is added during the sulfination. The reaction mixture is centrifuged and the residue removed from the centrifuge vessel with dilute mineral acid. The resulting suspension is extracted with diethyl ether, the solution is evaporated, and the *p*-dodecylbenzenesulfinic acid residue in 53 % yield is dried, *mp* 54–55 °C.

1-Dodecanesulfinic Acid [49]. A solution of 70 g (0.13 mol) tridodecylaluminum in 78 mL of toluene is added dropwise over 15 min to a mixture of 60 g (0.95 mol) of sulfur dioxide and 240 g of toluene at − 45 °C. The reaction mixture is allowed to warm to room temperature and the solvent is removed by distillation in vacuo. The residue is the aluminum salt of dodecylsulfinic acid, from which the sulfinic acid is liberated in 98 % yield, *mp* 35 °C.

Sulfur dioxide also reacts with aromatic hydrocarbons and aluminum trichloride to give sulfinic acids by a Friedel–Crafts-type mechanism [25,40]. Alkanes react as well under high pressure to give the corresponding alkyl sulfinic acids [51], and alkenes undergo the same reaction at atmospheric pressure. Photochemical sulfinations of alcohols in liquid sulfur dioxide [52] and of alkenes and alkanes in the gas phase are also known [53]. Sulfination of aromatic diazonium salts with sulfur dioxide in the presence of copper salts or copper powder is often used for the synthesis of sulfinic acids [26,43]. For the preparation of sodium 2,2,2-trifluoro-1,1-dichloroethanesulfinate see [54].

3.3. Oxidation of Thiols

Thiols can be easily oxidized to sulfinic acids, but it is often difficult to limit the oxidation of sulfur to the +4 state [55]. Halogens [56], hydrogen peroxide, and peracids [40] have been used as oxidizing agents. *m*-Chloroperbenzoic acid is particularly applicable because it does not result in further oxidation to sulfonic acids or sulfones [10]:

Ethanesulfinic Acid [10]. A solution of 17.2 g (0.1 mol) *m*-chloroperbenzoic acid in 200 mL of dichloromethane at − 30 °C is added slowly to a solution of 3.1 g (0.05 mol) of ethanethiol in 10 mL of dichloromethane (also at − 30 °C). The reaction mixture is allowed to stand overnight at − 30 °C and the precipitated *m*-chlorobenzoic acid is removed by filtration. The filtrate is cooled to − 80 °C and refiltered to remove residual *m*-chlorobenzoic acid, after which the solvent is evaporated in a stream of nitrogen. Analytically pure ethanesulfinic acid is obtained in 80–85 % yield.

The oxidation of 2-mercaptobenzo-1,3-thiazole with hydrogen peroxide in alkaline medium gives the sodium salt of benzo-1,3-thiazole-2-sulfinic acid, which (see Chap. 2) is converted immediately upon acidification into benzo-1,3-thiazole (**2**, 70 %) [39].

3.4. Nucleophilic Cleavage of Sulfones and Related Compounds (→ Sulfones and Sulfoxides)

Cleavage of the Sulfonyl Group at the α-Carbon Atom. The cleavage of aromatic sulfones carrying electron-withdrawing groups on the aromatic ring constitutes a general method for the synthesis of aromatic sulfinic acids [57]:

Intramolecular rearrangement (Smiles rearrangement) of the lithium salt of 2-hydroxyphenyl phenyl sulfone gives lithium 2-phenoxyphenylsulfinate (**3**) [58]:

The reaction of 2-methylphenyl phenyl sulfone (**4**) with butyllithium is similar to the Smiles rearrangement [29]:

For further information see [59]; for electrochemical cleavage of sulfones see [60].

The facile cleavage of symmetrical aliphatic sulfones with sodium cyanide when both β-positions are activated by electron-withdrawing substituents is of greater interest [30]:

Similarly, α-disulfones are readily cleaved with sodium cyanide [14], and β- cyanosulfones with sodium thiolate (see below) [61]. Furthermore, the cleavage of phthalimidomethyl sulfones with alkoxide or thiolate proceeds smoothly to give sulfinic acids in high yield [12]:

If the cleavage is carried out using thiolate, a phthalimidomethyl sulfide is formed as a byproduct. This sulfide can be reoxidized and itself cycled through the cleavage process, a reaction that permits the high-yield conversion of any thiol to the corresponding sulfinic acid.

General Example [12]. An alkylsulfonylmethylphthalimide (0.02 mol) is added to a solution of 0.51 g (0.022 mol) of sodium ethoxide in 65 mL of ethanol under nitrogen. The reaction mixture is stirred under reflux until a homogeneous solution is formed. After evaporation to dryness the residue is extracted several times with warm benzene. The sulfinate remains as an insoluble powder in a 92 – 100 % yield, purity 94 – 98 %.

Cleavage of Thiosulfonic Acid Esters. The cleavage of thiosulfonates with thiolate [62], sulfinate [63], and hydroxyl ions [64] can also be used for the preparation of sulfinic acids:

Cleavage at the β-Carbon Atom of a Sulfonyl Group. Both sulfones with β-hydrogens [65] and β-disulfones [66] undergo fragmentation with base to give the corresponding sulfinic acid salts:

The following reaction sequence also gives high yields of sulfinic acids [67]:

In addition, sulfinic acids can be prepared by alkylation of sulfonyl carbanions with subsequent elimination of sulfinate [68, 69]:

Cleavage of Sulfolenes. The ring-opening of a cyclic sulfone with a Grignard reagent represents another synthetic possibility. For example, in the case of 2-methylsulfolene (**5**) the product is a doubly unsaturated sulfinic acid [70]:

5

Addition of Thionyl Chloride to an Olefin with Subsequent Hydrolysis. Thionyl chloride adds to olefins in the presence of aluminum trichloride forming a complex that can be hydrolyzed with water to a sulfinic acid [71]:

For further syntheses see [72].

4. Reactions of Sulfinic Acids and their Derivatives

4.1. Alkylation of the Sulfinate Anion

The sulfinate anion can be alkylated either at sulfur or oxygen depending on the reaction conditions, forming a sulfone or a sulfinic acid ester, respectively. Reaction with a soft alkylating agent (in the sense of the Pearson HSAB principle [73–75]) such as an alkyl halide, gives a sulfone [76]:

Hard alkylating agents, such as triethyloxonium tetrafluoroborate [77] or diazomethane [78], give sulfinic acid esters:

The solvent may also have a significant effect on the observed ratio of sulfone to sulfinic acid ester [79].

The alkylation reaction is an effective approach to preparing dialkyl sulfones, aralkyl sulfones, and β-hydroxysulfones [75, 80–82]. Reaction of sulfinates with epoxides leads to β-hydroxysulfones [83]; with lactones, sulfonylcarboxylic acids are formed [84]. Sulfones are also formed by the reaction of sulfinates with systems containing activated double bonds [85–87]. Formaldehyde reacts with sulfinate to give hydroxymethyl sulfone [88]. Simultaneous addition of an amine leads to an *N*-methylsulfonylamine in a reaction analogous to the Mannich reaction [89]. On the other hand, diaryl sulfones are obtained by nucleophilic substitution of haloaromatics containing electron-withdrawing substituents (e.g., 2-nitrochlorobenzene) [90]:

[*1-(Phenylsulfonyl)-aceto*]-*4-nitrobenzene* [82]. 244 g (1 mol) of (1-bromoaceto)-4-nitrobenzene and 164 g (1 mol) of sodium benzenesulfinate are suspended in 1 L of ethanol and boiled for 4 h. After cooling, the precipitate is separated by filtration, boiled with acetone, and filtered again. The filtrates are combined, evaporated, and cooled. The crystalline sulfone is isolated by filtration in 76 % yield, *mp* 138 °C.

For the synthesis of thioacylic sulfones see [91].

4.2. Addition of Sulfinic Acids to Multiple Bonds

Polarized double-bond systems react with aliphatic and aromatic sulfinic acids in a process similar to the Michael reaction. Acrylic acids and their derivatives [92], vinyl ketones [93], nitroolefins [94], vinyl sulfones [95], quinones [96–98], and quinone imines [98] all undergo this reaction with sulfinic acids to form sulfones; e.g.:

The addition of a sulfinic acid to an α-ethynyl ketone sulfone gives an α-oxo-β-sulfonylalkene in good yield [99]. A *cis*-1,2-disulfonylethylene is formed with 1-phenylsulfonylpropyne [100].

4.3. Redox Reactions of Sulfinic Acids

Sulfinic acids are readily oxidized to sulfonic acids by, for example, peroxides [101], hypochlorites [102], and oxygen [103]. α-Disulfones are formed with permanganate or cobalt(III) salts [104]. The reduction of sulfinic acids with lithium aluminum hydride gives disulfides [105]. As they are relatively unstable compounds, sulfinic acids undergo acid-catalyzed disproportionation to sulfonic acids and thiosulfonates [15, 16, 35–37].

5. Sulfinic Acid Derivatives

5.1. Sulfinyl Chlorides

5.1.1. Preparation

From Disulfides. Both aliphatic and aromatic sulfinic acids form sulfinyl chlorides. Low yields are generally obtained from the direct reaction of a sulfinic acid with thionyl chloride [106], but chlorination of a disulfide has proven to be an effective method of synthesis. The chlorination is carried out at 0 – 10 °C in acetic anhydride [107, 108]:

The course of the reaction is clearly indicated by the disappearance of the orange-red color of the intermediate sulfenyl chloride (RSCl).

Methanesulfinyl Chloride [107]. A mixture of 23.5 g (0.25 mol) of freshly distilled dimethyl disulfide and 51 g (0.5 mol) of acetic anhydride is chlorinated at − 10 to 0 °C. During the course of the reaction the color changes from yellow to red and then disappears, at which point the addition of chlorine is suspended, leading to 126 g of reaction mixture. This is distilled in a 45 cm Vigreux column at 2 kPa with cooling. Acetyl chloride distills at 0 °C, and at 47 – 48 °C the almost colorless methanesulfinyl chloride is obtained in 83 – 86 % yield.

Many sulfinyl chlorides decompose to varying degrees in the course of distillation, and in aromatic cases there is even a danger of explosion. Sulfinyl chlorides may also decompose slowly during storage, causing pressure to build up in a closed container.

From Trithianes. Chloromethanesulfinyl chloride (**7**) can be prepared by the chlorination of trithiane (**6**) in acetic anhydride at 0 °C [109]:

Chloromethanesulfinyl Chloride. A mixture of 46 g (0.33 mol) of *sym*-trithiane (**6**) and 102 g (1 mol) of acetic anhydride is chlorinated at 0 °C. Residual chlorine and resulting acetyl chloride are evaporated in vacuo and the chloromethanesulfinyl chloride (**7**) is distilled in 55 % yield (*bp* 42 – 62 °C at 2 kPa).

For α-heteroatom-substituted methanesulfinic acids and their derivatives see [110]; for the synthesis of trimethylammoniomethanesulfinate see [111].

From Sulfuranes ($RSHal_3$). The selective hydrolysis of sulfurane also gives a sulfinyl halide [112]:

For the photolytic addition of sulfur dioxide to perfluoroalkenes giving sulfinyl fluorides see [113].

Trichlorosulfuranes [114, 115] are converted into sulfinyl chlorides in high yield in alcohol [116], carboxylic acids [117], or acetic anhydride [118]:

Because of the instability of sulfuranes, the compounds are usually synthesized immediately prior to use by further chlorination of the corresponding sulfenyl chloride.

From Thioesters. Another method for producing sulfinyl chlorides involves the chlorolytic cleavage of thioesters in acetic anhydride, leading to a mixture of the desired sulfinyl chloride and acetyl chloride [119]:

8

Phenylsulfinyl Chloride (**8**) [119]. A mixture of 30.4 g (0.2 mol) of phenyl thioacetate and 20.4 g (0.2 mol) of acetic anhydride is chlorinated at − 10 to 0 °C. The color changes to yellow, then red, and then back to yellow. The reaction mixture is heated to 80 °C under reduced pressure (3.5 kPa), until the residue begins to boil, after which it is cooled; yield of **8**: 31.5 – 31.8 g (98.1 – 99.1 %).

By the Addition of Thionyl Chloride to Alkenes. Addition of ethylene to thionyl chloride in the presence of aluminum trichloride gives the corresponding acid chloride complex, which upon hydrolysis forms 2-chloroethanesulfinic acid (**9**) [71]:

2-Chloroethanesulfinic Acid (**9**) [71]. A mixture of 32 g (0.27 mol) of thionyl chloride and 32 g (0.24 mol) of aluminum trichloride is saturated with 6 L (0.27 mol) of ethylene. The reaction mixture is hydrolyzed with water and the resulting byproducts are extracted with benzene. The residue is extracted with diethyl ether, which is then dried over magnesium sulfate and evaporated in vacuo. The yield of **9** is 98 %.

By Treatment of CH-Acidic Compounds with Thionyl Chloride. CH-acidic compounds react readily with thionyl chloride to give sulfinyl chlorides. For example, formylsulfinyl chloride can be obtained from isobutyraldehyde (2-methylpropanal) in 81 % yield [120]:

10

1-Formyl-1-methylethanesulfinyl Chloride (**10**) [120]. 72 g (1 mol) of 2-methylpropanal is

added dropwise to 360 g (3 mol) of thionyl chloride at 50 °C with cooling. As soon as the vigorous production of hydrogen chloride has subsided, the temperature is raised to 80 °C. When hydrogen chloride formation ceases completely excess thionyl chloride is removed by distillation at atmospheric pressure and the residue is distilled under vacuum, leading to 124 g, of **10**, *bp* 83 – 84 °C at 1.6 kPa.

For an analogous synthesis of adamantanesulfinyl chloride in 72 % yield see [121].

5.1.2. Reactions

Sulfinyl chlorides are important starting materials for the preparation of sulfinic acid esters (see Section 5.2) and amides (Section 5.4), as well as thiosulfinic acid esters (Section 5.3). For a transformation of sulfinyl chlorides into sulfines ($R_2C{=}S{=}O$) see [122]. Phenylsulfinyl chloride can be converted into a diarylthiosulfonate ester in dichloromethane in the presence of pyridine and 1-hydroxypyridine-2-thione [123].

Asymmetric aromatic sulfoxides can be prepared by the Friedel – Crafts reaction of an aromatic sulfinyl chloride with a benzene derivative [124, 125].

5.2. Sulfinic Acid Esters

5.2.1. Preparation

From Sulfinyl Chlorides and Alcohols. Sulfinic acid esters are readily prepared from sulfinyl chlorides and alcohols in an inert solvent [126]:

The hydrogen chloride formed can be removed by applying a vacuum [126], or by the addition of a base such as potassium carbonate [127] or pyridine [128]. For a one-pot synthesis of sulfinic acid esters (50 – 88 %) see [129].

Methyl Methanesulfinate [126]. A mixture of 47 g (0.5 mol) of dimethyl disulfide and 102 g (1 mol) of acetic anhydride is chlorinated to give methanesulfinyl chloride. The latter is then treated with 35 g (1.1 mol) of cold anhydrous methanol at – 30 °C. Hydrogen chloride is removed by applying a vacuum and the reaction mixture is heated to 30 °C until gas formation has ceased. *p*-Toluidine can be added to assist in the removal of methanesulfinyl chloride. The reaction mixture is filtered and the filtrate is distilled using an 18 cm Vigreux column in yield 71 %.

From Disulfides by Chlorination in Alcohol. If chlorination of a disulfide to give the corresponding sulfinyl chloride is carried out in an alcohol, the sulfinic acid ester is obtained directly [130]:

The oxidation of disulfides with lead tetraacetate in alcohol also leads to sulfinic acid esters in 30 – 90 % yield [131]. For an analogous reaction with diphenyl disulfide see [132]. Electron-withdrawing substituents on the aromatic ring inhibit this oxidation. *N*-Bromsuccinimide also acts as an oxidizing agent in the synthesis of

sulfinic acid esters (5 – 78 % yield) [133]. For cyclic sulfinic acid esters see [134].

Other Methods. The preparation of sulfinic acid esters from sulfinyl chlorides and diazoalkanes in polar solvents is described in [135] and from sulfinic acids and diazomethane in [78].

The reaction of benzenesulfinyl chloride with diazomethane is described in [109]. 4-Methylbenzenesulfinic acid reacts with diphenyldiazomethane in dichloromethane to give a sulfone as the major product, but in dimethylsulfoxide the sulfinic acid ester is formed in 100 % yield [135]. Another route involves the reaction of a sulfinate with a hard alkylating agent [78] (see Section 4.1).

Unlike carboxylic acids, sulfinic acids cannot be esterified by acid catalysis because under these conditions they disproportionate to sulfonic acids and thiosulfonates [15, 16, 35–37] (Section 4.3). However, esterification can be accomplished in a large excess of alcohol in the presence of dicyclohexyl carbodiimide [136]:

Sulfinic acid esters can also be obtained in good yield by the alcoholysis of *N*-sulfinylphthalimides [137]:

Synthesis of sulfinic acid esters by the alcoholysis of *N*-sulfinylsulfonamides is described in [138].

5.2.2. Reactions

Rearrangements. Alkane-, alkene, and alkynesulfinic acid esters undergo acid-catalyzed rearrangement to sulfones [139]; for example:

For further information see [140].

Conversion into Sulfoxides. Sulfinic acid esters react with Grignard reagents to give optically active sulfoxides [141]:

This reaction is highly stereospecific, and is, therefore, frequently used for the determination of absolute configurations.

Claisen Condensation. The Claisen condensation (→ Esters, Organic, Chap. 3.5.) of sulfinic acid esters with enolates leads to β-oxosulfoxides [142, 143], which can also be obtained by the reaction of sulfinyl carbanions with carboxylic acid esters:

For further reactions (e.g., the transformation of sulfinic acid esters into disulfides) see [144]. Information about MS-Research of sulfinic acid esters in [145].

5.3. Thiosulfinic Acid Esters

Thiosulfinic acid esters are readily prepared from the corresponding disulfides by careful oxidation with, for example, *m*- chloroperbenzoic acid [2]. Allicin (**1**) can be obtained in good yield by this method.

The disproportionation of sulfinyl chlorides in water also gives thiosulfinic acid esters [146]. For further references see [147].

5.4. Sulfinic Acid Amides

Sulfinic acid amides can be readily produced from sulfinic acid chlorides and amines:

The reaction is carried out in inert, dry solvents in the presence of base or excess amine [148–150].

General Method of Preparation [149]. Sulfinyl chloride (0.2 mol) is added dropwise to a solution of 0.4 mol of amine in 150 mL of dichloromethane under nitrogen in the course of 1 h. The temperature of the reaction mixture is maintained at − 20 to − 40 °C. It is stirred for a further hour at room temperature, after which ammonium chloride is filtered off. The filtrate is concentrated by evaporation, and the product is distilled in vacuo or crystallized.

Sulfinic acid amides can also be prepared by the reaction of sulfinylamines with Grignard reagents [72, 151, 152]:

Good yields are obtained with aromatic sulfinylamines. The Grignard complex should be decomposed carefully with 10 % cold ammonium chloride solution.

For a discussion of the preparation of *N*-sulfinylnonafluorobutanesulfonamide via an ene reaction and its subsequent conversion into the sulfine – sulfone imide see [138].

Sulfinic acid amides can also be prepared directly by the oxidation of sulfenic acid amides. Thus, 2-benzo-1,3-thiazolesulfenamides can be transformed into 2-benzo-1,3-thiazolesulfinamides by careful oxidation. The latter can be used as vulcanization accelerators for natural and synthetic rubbers [150]. Sodium hypochlorite is generally used as the oxidizing agent [150]:

Percarboxylic acids and hydrogen peroxide are also suitable.

N,N-Dicyclohexyl-2-benzo-1,3-thiazolesulfinic Acid Amide [153]. A 15 % aqueous sodium hypochlorite solution (150 g) is added dropwise over 10 minutes to a suspension of 48.3 g of *N,N*-dicyclohexyl-2-benzo-1,3-thiazolesulfenamide in 300 mL of methanol. The reaction mixture is boiled for 1 h and then cooled to 0 °C. The product is collected by filtration, washed, and dried; *mp* 135 –137 °C.

Additional references regarding the preparation of benzo-1,3-thiazolesulfinic acid amides in yields of ca. 90 % can be found in [154].

6. 1-Hydroxyalkanesulfinates

The sodium salt of a 1-hydroxyalkanesulfinic acid was first prepared by Bazlen in 1904 [155, 156].

6.1. Properties

Sodium hydroxymethanesulfinate [*149-44-0*] is commercially available as the dihydrate $HOCH_2SO_2Na \cdot 2\,H_2O$, which crystallizes as white needles, *mp* 63 °C. Its solubility in water at room temperature is 60 g/100 g. The salt is sparingly soluble in alcohol, and can be easily obtained pure from 60 % methanol. In moist air it decomposes slowly to products with noxious odors. The water of crystallization is lost upon heating to 120 °C, and then from 125 °C the compound undergoes a very exothermic decomposition to methanethiol, hydrogen sulfide, some formaldehyde, and sulfur dioxide, during which the temperature rises to 160 °C. The residue consists of sodium hydroxymethanesulfonate, sodium thiosulfate, and sodium sulfite. In solution the decomposition is pH and temperature dependent. Sodium hydroxymethanesulfinate reacts with sodium hydrogen sulfite to give sodium dithionite ($Na_2S_2O_4$) and sodium hydroxymethanesulfonate. The hydroxyl group is acidic and susceptible to salt formation.

The monozinc salt of hydroxymethanesulfinic acid $(HOCH_2SO_2)_2Zn$ is readily soluble in water, but zinc oxidomethanesulfinate $(OCH_2SO_2)Zn$ is only sparingly soluble. The former crystallizes from water at 80 °C in anhydrous form, at 60 °C as the trihydrate, and

at 20 °C as the tetrahydrate (rhombohedric leaflets). By contrast, the sparingly soluble dizinc salt precipitates from cold solution as a trihydrate and from warm solution as a monohydrate. The amorphous and crystalline calcium salts of hydroxymethanesulfinic acid and also zinc 1-oxidoethanesulfinate have been described as well. The latter is readily cleaved, and acts as a reducing agent at 50 °C. Derivatives of other aldehydes, such as benzaldehyde and butyraldehyde, also decompose readily, reducing vat dyes even at low temperature (see Chap. 8). The nature of sodium hydroxymethane sulfinate in aqueous solution is described in detail in [157].

6.2. Production

Sodium hydroxymethanesulfinate can be prepared by reacting sodium dithionite with formaldehyde in the presence of alkali, or by catalytic reduction of sodium hydroxymethanesulfonate with hydrogen. It also results from the zinc dust reduction of sodium hydroxymethanesulfonate, which is in turn prepared in situ from zinc oxide, sulfurous acid, and formaldehyde. A variant of this process involves the reduction of aqueous sulfur dioxide (sulfurous acid) with zinc dust to zinc dithionite, which is then converted with formaldehyde into the zinc salts of hydroxymethanesulfonic and hydroxymethanesulfinic acids. The sulfonic acid portion is reduced to the desired sulfinic acid salt in the presence of zinc and sodium hydroxide:

$$Zn + 2SO_2 \xrightarrow{H_2O} ZnS_2O_4$$

$$ZnS_2O_4 + 2H_2O + 4CH_2O \longrightarrow (HO-CH_2-SO_3)_2Zn + (HOCH_2-SO_2)_2Zn$$

$$(HOCH_2-SO_3)_2Zn + 2Zn \longrightarrow 2(-OCH_2-SO_2)Zn + ZnO + H_2O$$

$$(-OCH_2SO_2)Zn \xrightarrow{NaOH} HOCH_2-SO_2Na + ZnO$$

General Synthesis. Zinc dust is suspended in 5 times its volume of water and sulfur dioxide is passed in at 30 – 35 °C until all the zinc has dissolved. Aqueous formaldehyde (30 – 40 %) is then added at 50 – 60 °C until the solution no longer reduces indigo in the cold. After addition of the calculated quantity of zinc dust, the reaction mixture is heated to 90 °C, and this temperature is maintained until virtually no more zinc compounds dissolve. Sodium hydroxide is subsequently added and the mixture is filtered. The clarified solution of sodium hydroxymethanesulfinate is evaporated in vacuo until it acquires the consistency of honey; $HOCH_2SO_2Na \cdot H_2O$ solidifies within a few hours, after which it can be ground.

The synthesis also produces zinc hydroxymethanesulfinate in soluble form, together with the zinc salt of the sulfonic acid. The former can be separated by evaporation in vacuo and subsequent drying. Zinc oxidomethanesulfinate can be obtained from zinc hydroxymethanesulfinate by the addition of zinc salts and sodium hydroxide. Other salts, such as the calcium salt, are precipitated by treating sodium hydroxymethanesulfinate with the appropriate chloride (e.g., $CaCl_2$). Other aldehydes can be used in place of formaldehyde to synthesize alternative hydroxyalkanesulfinic acids. Many aldehydes have been shown to be effective [156]. Hydroxyalkanesulfinic acids are intermediates in the reduction of aldehydes and ketones with dithionite [158].

6.3. Quality Specifications, Analysis

The industrially important salts of hydroxymethanesulfinic acid decompose in moist air. Their packaging must, therefore, provide protection against air and moisture. The products present neither a fire hazard nor a tendency to self-ignite.

Sodium hydroxymethanesulfinate is commercially available in 98 – 100 % purity; sodium hydroxymethanesulfonate and sodium sulfite are present as impurities. The commercial zinc salt contains 88 – 90 % sulfinate based on anhydrous product. The main impurities in this case are sodium sulfate and zinc hydroxymethanesulfonate. The proportion of sulfinate in the calcium salt is 70 % based on anhydrous product, with the corresponding reactants present as impurities. Other salts of industrially produced alkanesulfinic acids (e.g., sodium hydroxy-1-ethanesulfinate) are avoided in pure form because of their odors.

The content of alkanehydroxysulfinate can be determined iodometrically in the absence of air.

The method is analogous to determination of the content of dithionite, in which titration is carried out with acidic indigo carmine solution. The required temperature for the titration depends on the nature of the aldehyde.

7. Formamidinesulfinic Acid

Formamidinesulfinic acid (**11**) [*1758-73-2*], $CH_4N_2O_2S$, is used in certain branches of the textile industry [159].

11

7.1. Properties

Formamidinesulfinic acid is a white crystalline compound, *mp* 128 °C (decomp.), in [159] *mp* 144 °C. It is sparingly soluble in water and other common solvents. The compound dissolves in alkaline solutions with decomposition, but it can be heated to 100 °C in concentrated sulfuric acid without decomposition. It reacts with formaldehyde and sodium hydroxide to form sodium hydroxymethanesulfinate, and with sodium hydrogensulfite to give sodium dithionite. Further information in the references given in [160]; for spectrochemical study see [161].

7.2. Production

Formamidinesulfinic acid was first obtained by Barnett, in 1910 by the oxidation of thiourea with hydrogen peroxide:

Since then a number of syntheses have been described in the literature, involving the use of hydrogen peroxide in a variety of solvents. Methanol: water (40 : 60) leads to formamidinesulfinic acid in 96.5 % yield and 98 % purity [162].

Formamidinesulfinic Acid (**11**) [162]. Thiourea (80 g) is dissolved in 800 g of methanol : water (40 : 60) at 20 °C and oxidized with 210 g of 35 % hydrogen peroxide at − 20 to − 10 °C over the course of 30 min. The reaction mixture is then stirred for a further 10 min. The product is obtained in 96.5 % yield and 98 % purity. For further information see [163].

Other synthetic procedures can be found in the literature, including oxidation of thiourea with chlorine dioxide [164], photochemical oxidation with singlet oxygen [165], and oxidation with hydrogen peroxide in water [166] or carbon tetrachloride [167]. Oxidation of substituted thioureas to the corresponding formamidinesulfinic acids has also been described [168].

Oxidimetric methods and titration with indigo in the presence of sodium hydrogencarbonate are suitable means for determining purity.

8. Industrial Uses of Sulfinic Acids and their Derivatives

Sulfinic acids and their derivatives are used in a wide range of industrial applications, serving as:

1) Catalysts for the polymerization of styrene, butadiene, and methacrylic acid esters at low temperature [10, 72], as well as for polymerization of acrylonitrile [169]
2) Catalysts for rapid and mild isomerization of disubstituted double bonds [170]
3) Surface-active agents for the pretreatment of raw cotton as a way to avoid bleaching [171]
4) Antistatic additives to facilitate dyeing of polyamides [172]
5) Agents to improve the dyeing of linear polyesters [173]
6) Additives for polyacrylonitrile solutions subject to spinning [174]
7) Plant-growth regulators [175], crop-protection agents [176, 177], and fungicides [178]
8) Fragrances and flavors for foods, perfumes, and tobacco [179, 180]
9) Activators for nitrogen- containing propellants [181] (e.g., azodicarbonamide [182])

10) Emulsifiers and dispersing agents for oil–water emulsions [183, 184], agents for floating ores [185]
11) Intermediates in the production of crease-resistant finishes [186]
12) Intermediates in the production of pharmaceuticals [187]
13) Antifogs in silver halide photography [188]
14) Agents for stimulating mucous membranes of the mouth and nose providing a cooling sensation similar to that of menthol [189]
15) Vulcanization accelerators [190, 191]
16) Reducing agents for dyes [192], as well as elsewhere in the dye industry [193]
17) Reducing agents for aldehydes and ketones [158, 194].

Several hydroxyalkanesulfinic acid salts are available commercially. For example, sodium hydroxymethanesulfinate is sold under the trade names Rongalite C [195] (BASF) and Brüggolit (Brüggemann, Germany), and as various Hydrosulfite formulations (Ciba-Geigy and Rohner). It is used mainly in direct and discharge printing for converting vat dyes into their leuco forms and as reducing catalyst for synthetic rubber thermoplastics and for bleaching polyesters. A redox potential corresponding to that of dithionite is attained only at 75–80 °C, so the reduction is carried out in a steam bath (→ Bleaching, Chap. 2.3.3.).

Zinc hydroxymethanesulfinate is sold under the trade name Decrolin (BASF) and as various Hydrosulfite preparations (Ciba-Geigy, Rohner, and Pechiney, France). The zinc salt is used in the wool industry and also as a bleaching agent for such materials as soaps, fatty acids, glycerol, sizing agents, and for corrosion color printing on polyamide, wool, silk etc.

Calcium hydroxymethanesulfinate is commercially available under the trade name Rongalite H (BASF). It is used for vat-dye printing on acetate, polyamide, silk, and wool fabrics. Such prints display exceptional stability toward storage.

Hydroxyalkanesulfinic acids derived from other aldehydes, such as acetaldehyde, benzaldehyde, or butyraldehyde, as well as products condensed with ammonia, are available under such trade names as Rongalite 2 PH–A and 2 PH–B_{fl} and Rongalite FD_{fl} (BASF). These vary in their redox potentials. For example, the redox potential of Rongalite 2 PH lies between those of Hydrosulfite and Rongalite C (sodium hydroxymethanesulfinate), and that of Rongalite FD is above Rongalite C. These products have proven useful in two-phase and fill printing as well as in the textile industry.

For the use of sulfinic acids as fungicides see [178], for other applications in the dye industry see [192, 193], and as reducing agents for aldehydes and ketones see [158, 194].

Formamidinesulfinic acid is sold under the trade names Reduktionsmittel F (Degussa) [196] GLO Lite TD (Glo-Tex Chemicals, United States), Arolite TD Concentrate (Arol Chemical Products Company, United States), Thio Urea Dioxide and tec light (Tohai Denka Kogya Co., Japan). Formamidinesulfinic acid can be used for the reduction of disulfides [197] and the hydrogenation of aldehydes [198], as a processing aid in noble-metal extraction [199], as a dye stabilizer for pyrazoline brighteners [200], as a bleaching agent in the paper industry [201], as an agent for improving silver halide photography [202], for anaerobic textile wastewater treatment [203], and for catalyzing the reactions of olefins with dibromodifluoromethane [204]. Further sulfinic acid salts for synthetic intermediates are available: 4-chlorobenzenesulfinic acid sodium salt (Rohner, Bayer) [205]; benzenesulfinic acid sodium salt (Bayer) [206], the analogous zinc salt (Rohner) [207]; 4-methylbenzenesulfinic acid sodium salt (Rohner) [208]; 4-nitrobenzenesulfinic acid sodium salt (Bayer) [209]; 4-chloro-3-nitrobenzenesulfinic acid sodium salt [210].

9. Toxicology

Published toxicological data regarding these compounds are sparse. The reported LD_{50} values are in the region of a few grams per kilogram. Benzenesulfinic acid is said to cause slight skin irritation [211, 112].

The LD_{50} value of sodium hydroxymethanesulfinate is ca. 6400 mg/kg (oral), that of zinc hydroxymethanesulfinate 1280 mg/kg oral, rat [213]. The former is slightly irritating to the mucous membranes, but not to the skin (Safety Data Sheet, Brüggolit C) [214]. The latter causes skin irritation and moderate mucous membrane irri-

tation [213]. Further LD_{50} values (oral, rat) for some sulfinic acid salts are listed below:

Formamidinesulfinic acid	1120 mg/kg skin irritant [196]
4-Chlorobenzenesulfinic acid sodium salt	> 5000 mg/kg [205]
Benzenesulfinic acid sodium salt	> 5000 mg/kg [206]
Benzenesulfinic acid zinc salt	> 5000 mg/kg [207]
4-Methylbenzenesulfinic acid sodium salt	3200 mg/kg [208]
4-Nitrobenzenesulfinic acid sodium salt	> 5000 mg/kg [209]
4-Chloro-3-nitrobenzenesulfinic acid sodium salt	> 5000 mg/kg [210]

In case of an emergency, the appropriate safety data sheets should be consulted for all these products.

1. Sulfites and Disulfites

1.1. General Properties

Sulfurous acid is formed on passing sulfur dioxide into water:

$$SO_2 + H_2O \rightleftharpoons H_2SO_3$$

Since the equilibrium lies almost completely on the left-hand side and gas hydrates are formed on cooling the solution, isolation of the anhydrous acid is not possible. The acid dissociates in two steps:

$$H_2SO_3 \rightleftharpoons H^+ + HSO_3^- \quad K_1 = 1.6 \times 10^{-2}$$

$$HSO_3^- \rightleftharpoons H^+ + SO_3^{2-} \quad K_2 = 1.0 \times 10^{-7}$$

The dissociation constants K refer to 25 °C [1]. At higher concentrations the disulfite ion is formed:

$$2\,HSO_3^- \rightleftharpoons S_2O_5^{2-} + H_2O$$

The neutral alkali-metal sulfites M_2SO_3 and hydrogensulfites $MHSO_3$ are readily soluble in water. The latter cannot be isolated, since they are converted to disulfites on concentrating the solution.

Sulfurous acid and its salts are used as reducing agents. Aqueous solutions of halogens are reduced to hydrogen halides, iodates to iodides, and dichromates to chromium(III). However, sulfurous acid behaves as an oxidizing agent in the presence of stronger reducing agents; for example, with sulfur, thiosulfates are formed.

1.2. Ammonium Sulfite [2]

Solutions of ammonium sulfite [*10196-04-0*], $(NH_4)_2SO_3$, M_r 116.13, are produced by treating sulfur dioxide with aqueous ammonia. They are mainly used for the production of ammonium thiosulfate.

1.3. Potassium Disulfite [3]

The industrial production of potassium disulfite [*16731-55-8*], $K_2S_2O_5$, M_r 222.31, is similar to that of sodium disulfite. It is used for combatting fungi on vines and in wine production.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a25_477

1.4. Sodium Disulfite [4]

Sodium disulfite [*7681-57-4*], $Na_2S_2O_5$, M_r 190.1, dissolves readily in water with the formation of sodium hydrogensulfite $NaHSO_3$ (see Fig. 1) [5].

Figure 1. Solubility of Na_2SO_3 and $Na_2S_2O_5$ in water as a function of temperature

The fine crystalline salt can be stored without any problem if kept cool, dry, and with the exclusion of air. When moist it is oxidized by atmospheric oxygen to the sulfate.

Sodium disulfite is produced by treating 50–70 % sodium hydroxide or a suspension of sodium carbonate with sulfur-dioxide-containing gases in saturated sodium hydrogensulfite solution (Fig. 2) [6–9]. The sodium disulfite is removed by centrifugation and then dried. The saturated mother liquor from the centrifuge is mixed with the liquor from the waste-gas scrubber and adjusted to the usual commercial concentration.

Sodium disulfite production is coupled with the formation of sodium hydrogensulfite solution, for which, therefore, a demand must also exist. Production processes that use an anhydrous route, involving treatment of sodium sulfite or sodium carbonate with sulfur dioxide, have not achieved industrial importance.

Equipment and storage containers are predominantly made from 1.4571 grade stainless steel. Fiberglass-reinforced plastic containers are also suitable for storage. Paper or plastic sacks, steel barrels, or big bags made of synthetic fibers are used for transportation.

The commercial product has a content of ca. 97 % $Na_2S_2O_5$, 1 – 2 % Na_2SO_3, and ca. 1 % Na_2SO_4.

Sodium disulfite is used in the photography and fiber industries, for preserving foodstuffs, for wastewater treatment, and in the paper, textile, and leather industries.

1.5. Sodium Hydrogensulfite [4]

Sodium hydrogensulfite [*7631-90-5*], $NaHSO_3$, M_r 104.06, is not known in the solid state. On concentrating an aqueous solution, solid sodium disulfite crystallizes. Sodium hydrogensulfite is oxidized in air. Solutions of high purity can be produced by dissolving sodium disulfite in water. Commercial solutions are produced as the mother liquor in the production of sodium disulfite or by treating a suspension of sodium hydroxide, or sodium sulfite or sodium carbonate with sulfur dioxide until a pH of 3.5 – 4 is reached. The equipment is mainly made of 1.4571 grade stainless steel. For storing the solution, fiberglass-reinforced plastic containers are also suitable.

1.6. Sodium Sulfite

Sodium sulfite [*7757-83-7*], Na_2SO_3, M_r 126.04, is predominantly marketed as the anhydrous salt. It is produced by treating a suspension of sodium hydroxide or sodium carbonate with sulfur dioxide. The temperature is maintained at 60 – 80 °C for optimal crystal separation. The sodium sulfite suspension formed is centrifuged and the salt dried. Some sodium sulfite is obtained from scrubbing of SO_2- containing off-gases. Production processes using an anhydrous route have not yet achieved industrial importance.

Sodium sulfite is sold in various purity grades containing 90 – 98 % Na_2SO_3. The salt can be stored for long periods if kept dry, with the exclusion of air. It is transported in plastic and paper sacks. Sodium sulfite is used as a reducing agent, for the production of sodium thiosulfate, in the photography, paper, and textile industries, for treating boiler water, and as a food preservative.

Figure 2. Production of sodium disulfite and sodium hydrogensulfite solution
a) Scrubber; b) Production plant; c) Centrifuge; d) Storage vessel for sodium hydrogensulfite solution

1.7. Analysis of Alkali-Metal Sulfites

The total sulfur dioxide content is titrated iodometrically. Sulfate is determined, after acidification of the solution with HCl and driving off the SO_2 with CO_2, either titrimetrically or as barium sulfate. To determine sulfite in sodium hydrogensulfite or sodium disulfite, the sample solution is treated with formalin and the NaOH liberated is titrated in the presence of phenolphthalein.

1.8. Toxicology

Oral administration of a few grams of sodium sulfite causes dizziness, vomiting, and diarrhoea [10]. Small doses of sodium hydrogensulfite are oxidized to sulfate in vivo, whereas larger doses cause considerable irritation of the gastrointestinal tract.

2. Thiosulfates

2.1. General Properties

Thiosulfates are the salts of thiosulfuric acid [*14921-76-7*], $H_2S_2O_3$. Whereas thiosulfuric acid is highly unstable, thiosulfates are quite stable, even in aqueous solution.

Most thiosulfates are readily soluble in water, with the exception of the moderately soluble barium salt and the sparingly soluble silver and lead salts. The soluble salts are readily crystallized. Acid salts do not exist.

The following properties are characteristic of thiosulfates: decomposition to sulfur and sulfur dioxide in acid solution:

$$S_2O_3^{2-} + 2\,H^+ \longrightarrow S + SO_2 + H_2O$$

decomposition in alkaline solution according to the equation:

$$S_2O_3^{2-} + 2\,OH^- \longrightarrow SO_4^{2-} + S^{2-} + H_2O$$

oxidation by weak oxidizing agents (I_2, Fe^{3+}, and Cu^{2+}) to give tetrathionate:

$$2\,S_2O_3^{2-} + I_2 \longrightarrow S_4O_6^{2-} + 2\,I^-$$

and oxidation by strong oxidizing agents (Cl_2, Br_2, MnO_4^-, and $Cr_2O_7^{2-}$) to give sulfate:

$$S_2O_3^{2-} + 4\,Cl_2 + 5\,H_2O \longrightarrow SO_4^{2-} + H_2SO_4 + 8\,HCl$$

The use of thiosulfates as antichlorines for removal of chlorine (e.g., from bleached materials) is based on the last-mentioned reaction. With heavy metals (e.g., silver) the thiosulfate ion forms soluble complexes $[Ag(S_2O_3)_2]^{3-}$. This property is used in photography for fixing.

Sodium and ammonium thiosulfates are important industrial chemicals.

2.2. Sodium Thiosulfate

Sodium thiosulfate is produced and sold as the anhydrous salt, and as the pentahydrate $Na_2S_2O_3 \cdot 5\,H_2O$. The hydrated product was formerly known as antichlorine, because of the earlier wide use for removal of residual chlorine.

Properties. Sodium thiosulfate [*7772-98-7*] crystallizes from aqueous solution as short, colorless prisms or elongated crystals. It effloresces in dry air, particularly at temperatures above ca. 33 °C. At 48 °C the crystals dissolve in their own water of crystallization. The solution tends to become supersaturated and can be kept in this state for weeks at room temperature. Spontaneous crystallization only occurs on supercooling to − 30 °C or below. On heating, preferably with stirring and under reduced pressure, the anhydrous salt is obtained as a heavy, white, crystalline powder. Anhydrous $Na_2S_2O_3$ is also produced by dehydration of $Na_2S_2O_3 \cdot 5\,H_2O$ in a stream of dry air at temperatures of up to 60 °C. At 223 °C sodium thiosulfate decomposes, predominantly giving sodium sulfate and pentasulfide:

$$4\,Na_2S_2O_3 \longrightarrow 3\,Na_2SO_4 + Na_2S_5$$

The pentahydrate, which exists in two modifications, is stable below 48 °C. Four modifications of anhydrous $Na_2S_2O_3$ are known [11].

Aqueous solutions of sodium thiosulfate are of neutral pH. They can be kept for months in the dark with the exclusion of air, but decompose on prolonged boiling in air. On addition of acid sulfur precipitates and sulfur dioxide is liberated. The densities of aqueous $Na_2S_2O_3$ solutions at 20 °C are listed below:

$[Na_2S_2O_3]$, wt %	ϱ, g/cm^3
1	1.0065
2	1.0148
4	1.0315
8	1.0654
10	1.0827
12	1.1003
16	1.1365
20	1.1740
24	1.2128
28	1.2532
30	1.2739
35	1.3273
40	1.3827

Table 1 lists the solubility in water; other properties are given in Table 2 and [12].

Production of sodium thiosulfate is based on the following reactions:

$$Na_2SO_3 + S \longrightarrow Na_2S_2O_3$$

$$2\,NaOH + SO_2 + S \longrightarrow Na_2S_2O_3 + H_2O$$

The raw materials are usually used in a technically pure form and consist of sulfur (solid or liquid), sodium sulfite, sodium hydrogensulfite, sodium hydroxide, and sulfur dioxide. The latter is used either as a pure gas or as a sulfur combustion gas containing ca. 18 % SO_2.

The addition of sulfur to sodium sulfite is carried out in stirred vessels. The reaction rate depends on the temperature, the excess of sulfur, and the intensity of stirring. The reaction lasts for several hours.

Polysulfide solutions are also produced to some extent as intermediates and react with disulfite to give thiosulfate [13]. Processes have also been described involving the production of sodium thiosulfate by oxidation of aqueous sodium sulfide solutions in the presence of catalysts [14–16] .

The sodium thiosulfate solutions are filtered hot, sometimes with the addition of decolorizing charcoal. The excess sulfur is recycled. The $Na_2S_2O_3 \cdot 5\,H_2O$ is crystallized by cooling the filtrate. The mother liquor still contains ca. 5 % $Na_2S_2O_3$ at 20 °C. Further sodium thiosulfate can be obtained from this mother liquor by evaporation. The crystalline salt is separated by centrifugation. The pentahydrate must be dried below ca. 40 °C because at higher temperatures water of crystallization is lost. Pneumatic-conveyor or fluidized-bed driers are used.

Anhydrous sodium thiosulfate is produced by dehydration of the pentahydrate at 60 –105 °C at atmospheric or reduced pressure. Another possibility is crystallization from sodium thiosulfate solution above 70 °C.

The standard commercial particle sizes are obtained by using continuous or batch crystallization equipment.

Quality Specifications and Analysis. For photographic purposes the degree of purity laid down in the ASA and DIN/ISO standards is usually adequate (99 % for $Na_2S_2O_3 \cdot 5\,H_2O$ and 97 % for anhydrous $Na_2S_2O_3$). The content of sodium thiosulfate is determined potentiometrically by titration of the diluted solution with iodine solution [17–19].

Both types of sodium thiosulfate are produced in Germany at Chemiewerk Bad Köstritz and anhydrous $Na_2S_2O_3$ is produced by Th. Goldschmidt AG, Werk Mannheim; Brotherton, England; and Foret, Spain, for example.

Table 1. Solubility of sodium thiosulfate in water

Solid phase	Ice		$Na_2S_2O_3 \cdot 5H_2O$			$Na_2S_2O_3 \cdot 2H_2O$			$Na_2S_2O_3 \cdot 0.5H_2O$			$Na_2S_2O_3$	
T, °C	−3.9	−11	0	20	40	48	50	60	65	70	75	80	100
wt %	15.0	30.0	34.4	41.2	50.6	62.0	62.9	67.4	69.5	70.0	70.8	71.0	72.7

Table 2. Properties of sodium thiosulfate

	$Na_2S_2O_3 \cdot 5H_2O$	$Na_2S_2O_3$
M_r	248.17	158.10
Crystal system	monoclinic	monoclinic
ϱ at 25°C, g/cm^3	1.749	2.267
Specific heat capacity at 0° C, J kg^{-1} K^{-1}	1 453	924
Heat of fusion, kJ/kg	148.1	
Heat of solution at 25°C, kJ/kg	190.6	
Heat of hydration at 18°C, kJ/mol	55.7	
Enthalpy of formation, kJ/mol	2 601	

Uses. Anhydrous sodium thiosulfate is now only added in small quantities to ammonium thiosulfate (see page 6). The hydrated salt is used as an antichlorine in bleaching, in wastewater purification, for reduction of dichromate in chromed leather production, and as a solvent for silver chloride in the chloride roasting of silver-containing minerals.

2.3. Ammonium Thiosulfate

Properties. Ammonium thiosulfate [*7783-18-8*], $(NH_4)_2S_2O_3$, crystallizes in an anhydrous form as shiny plates or sword-shaped crystals. No hydrates are known. On heating to 150 °C it sublimes with partial decomposition into $(NH_4)_2SO_3$, S, NH_3, and H_2S. Ammonium thiosulfate is hygroscopic; the stability limit is at 64 % relative humidity. It is readily soluble in water, sparingly soluble in acetone, and insoluble in alcohol. The solubility in water is lowered by the presence of NH_3. The solubilities are listed in Table 3. The densities of aqueous solutions at 20 °C are listed below:

$[(NH_4)_2S_2O_3]$, wt %	ϱ, g/cm^3
56	1.303
57	1.310
58	1.314
59	1.319
60	1.324
61	1.329
62	1.334

Table 3. Solubility of ammonium thiosulfate

T, °C	Solubility	
	in water	in NH_3-saturated water
0	60.0	
10	61.6	
20	63.1	25.8
30	64.7	38.1
40	66.3	46.5
50	67.9	58.2
60	69.4	65.9
70	71.0	70.7
80	72.6	72.4
90	74.2	

The data are for technical grades, which contain ca. 0.2 % NH_3 and small quantities of sulfate and sulfite. Aqueous ammonium thiosulfate solutions decompose slowly on heating above 40 °C with formation of sulfur and sulfate. A small quantity of sulfite stabilizes the solutions considerably. Some other properties are as follows:

100 % $(NH_4)_2S_2O_3$	
M_r	148.20
Crystal system	monoclinic
ϱ at 25 °C, g/cm^3	1.71
Heat of solution, water, 25 °C, kJ/kg	105
58–60 % $(NH_4)_2S_2O_3$ (aq.)	
Thermal conductivity, kJ m^{-1} h^{-1} K^{-1}	1.84
Specific heat capacity, kJ kg^{-1} K^{-1}	2.45
Vapor pressure, kPa	
20 °C	1.7
40 °C	5.4
60 °C	14.2

Production of ammonium thiosulfate is based on the reaction of sulfur, or occasionally ammonium sulfide and polysulfides [20], with ammonium sulfite in an aqueous ammoniacal medium. The ammonium sulfite is produced from ammonia or ammonia – water and SO_2 in the same or in a separate process step:

$$2\,NH_3 + SO_2 + H_2O \longrightarrow (NH_4)_2SO_3$$

$$(NH_4)_2SO_3 + S \longrightarrow (NH_4)_2S_2O_3$$

The sulfur dioxide is used neat (gaseous or liquid) or as sulfur combustion gas, and sulfur is used in liquid or solid form.

The rate of reaction of sulfur with ammonium sulfite depends on the temperature, the intensity of stirring, and the excess of sulfur. At 110 °C the reaction is complete after 1 – 2 h. Increased pressure with higher reaction temperatures and shorter reaction times can also be used [21]. A one-step process is also possible. Solutions containing ca. 60 % ammonium thiosulfate are produced to be sold as such, and 70 – 72 % solutions for production of the solid salt. The latter are filtered hot, sometimes with the addition of charcoal. The 60 % solutions can be filtered hot or after cooling.

To obtain the salt the filtered solution is cooled to ca. 20 – 30 °C. The crystallized salt is separated by using sieve-screw centrifuges. Drying must be carried out carefully; a product temperature of 50 °C must not be exceeded. The ca. 60 % mother liquor is recycled.

Crystalline ammonium thiosulfate tends to cake. It can be rendered free-flowing by the addition of 5 – 10 % anhydrous sodium thiosulfate (ammonium thiosulfate 90/10). The stability to storage is increased by the addition of ca. 1 – 2 % Na_2SO_3. The stability to storage of ammonium thiosulfate solutions can be increased by adding $(NH_4)_2SO_3$ or Na_2SO_3.

Ammonium thiosulfate can also be produced by the reaction of ammonium polysulfide solutions with gaseous SO_2 [22], [23]. In a process developed by the company Foret $(NH_4)_2S_2O_3$ is obtained from H_2S, NH_3, and water at ≤ 45 °C in the first step and subsequent reaction with SO_2 [23], [24].

Quality Specifications and Analysis. Commercially the degrees of purity and analysis methods laid down in the ASA, DIN, and ISO standards are valid [17–19] (see Table 4). In some cases particle size and particle-size distribution are also specified.

Table 4. Specifications for photo-quality ammonium thiosulfate

Analysis	Solid (ASA)	Aqueous solution (DIN 19 080 T82, ISO 3619)
$(NH_4)_2S_2O_3$, wt %	> 97	57 – 61
Sulfite (as SO_3), wt %	≤ 1.4	≤ 0.7
Sulfite [as $(NH_4)_2SO_3$], wt %		max. 1
H_2O, wt %	≤ 0.5	–
$(NH_4)_2S$, ppm	≤ 10	≤ 5
Insolubles, wt %	≤ 4	≤ 0.2
Combustion residue, wt %	≤ 2	≤ 0.2
Heavy metals (as Pb), ppm	≤ 20	≤ 10
Iron, ppm	≤ 50	≤ 10

Titration with iodine solution gives the combined thiosulfate and sulfite content; titration in the presence of formaldehyde gives the thiosulfate content.

Uses. Ammonium thiosulfate is used almost exclusively as a photographic fixing salt. Its advantage compared with sodium thiosulfate lies in the shorter fixing times, the increase in the efficiency of the fixing baths by ca. 50 %, and shorter washing periods. The recovery of the silver from spent fixing baths is easier. In Western Europe almost only ammonium thiosulfate is now used for fixing. By far the greatest proportion of the demand is covered by solutions.

The following are commercially available as solids:

Ammonium thiosulfate	98/100
Ammonium thiosulfate	90/10
Rapid fixing salt U3	70 % $(NH_4)_2S_2O_3$
Rapid fixing salt U3	20 % $Na_2S_2O_5$
Rapid fixing salt U3	10 % $Na_2S_2O_3$

Some producers of ammonium thiosulfate in Europe are: Th. Goldschmidt; Chemiewerk Bad Köstritz, Germany; Foret, Spain; W. Blythe & Co., United Kingdom.

2.4. Toxicology

For *sodium thiosulfate*, the LDLo for subcutaneous application in rabbits is 4000 mg/kg, and in frogs 6000 mg/kg [25].

For $Na_2S_2O_3 \cdot 5\,H_2O$, the oral TDLo in humans is 300 mg/kg (oral intake during 7 days). For dogs, the intravenous LDL_0 is 3000 mg/kg [25].

According to [26], $Na_2S_2O_3 \cdot 5\,H_2O$ has low oral toxicity. Larger doses (up to 12 g daily) have a severe laxative effect.

The following values have been determined for *ammonium thiosulfate* [25]: LD_{50} (oral, rat) 2890 mg/kg, LD_{50} (oral, guinea pig) 1098 mg/kg.

3. Sodium Dithionite [27]

3.1. Introduction

Sodium dithionite [*7775-14-6*], $Na_2S_2O_4$, is the only industrially important salt of dithionous acid ($H_2S_2O_4$), which has not been isolated. The importance of sodium dithionite lies in its powerful reducing capacity, which allows, for example, vat dyes to be reduced at room temperature. It is also used as a bleaching agent, mainly in the textile and paper industries.

STAHL first prepared dithionite unwittingly in 1718 when he treated iron with aqueous sulfur dioxide and obtained a yellow solution. In 1789 BERTHOLET showed that no hydrogen was produced in this reaction. In 1852 SCHÖNBEIN used this solution for the reduction of indigo. SCHÜTZENBERGER isolated dithionite as the dihydrate and gave it the name hydrosulfite. In 1881 BERNTHSEN established that hydrosulfite did not contain any hydrogen, but corresponded to the formula $Na_2S_2O_4$. In 1905 BAZLEN introduced the zinc-dust process for the production of anhydrous sodium dithionite. He also suggested using sodium amalgam as reducing agent.

3.2. Properties

Sodium dithionite is known as the dihydrate $Na_2S_2O_4 \cdot 2\,H_2O$, M_r 210.146, and as the anhydrous salt, M_r 174.114. The dihydrate crystallizes in thin, yellowish shiny, soft prisms of density 1.58 g/cm^3. The anhydrous salt forms monoclinic white crystals of density 2.38 g/cm^3. The solubility in water of both forms is shown in Figure 3. Solutions with anhydrous undissolved solute are labile below 72 °C. The solubility and the position of the transformation point are strongly influenced by foreign salts, particularly sodium salts, and water-miscible organic solvents.

Figure 3. Solubility of sodium dithionite in water

Sodium dithionite dihydrate is very sensitive toward atmospheric oxygen in the finely crystalline state. The heat of oxidation can lead to ignition. The anhydrous salt decomposes exothermically in air on prolonged heating above 90 °C. The main decomposition products are sodium sulfate and sulfur dioxide. Above ca. 150 °C, with exclusion of air, sodium dithionite decomposes in a vigorous reaction, giving mainly sodium sulfite, sodium thiosulfate, sulfur dioxide, and a small amount of sulfur. In the absence of air, moisture only causes a small degree of decomposition. Sodium dithionite in powder form can decompose in air on contact with a small amount of water with such intense heat formation that it burns with a flame.

Aqueous dithionite solutions decompose slowly in the cold and rapidly in the warm, whereby hydrolysis to hydrogensulfoxylate and hydrogensulfite occurs first. The hydrolysis products can be trapped as sodium 1-hydroxyalkane-sulfinates and 1-hydroxyalkanesulfonates by addition of aldehydes or ketones:

$$NaO_2S - SO_2Na + H_2O \longrightarrow NaHSO_2 + NaHSO_3$$

$$NaHSO_2 + CH_2O \longrightarrow HOCH_2SO_2Na$$

$$NaHSO_3 + CH_2O \longrightarrow HOCH_2SO_3Na$$

In weakly acidic solution dithionite decomposes rapidly, especially under warm conditions, to give the thiosulfate and disulfite or hydrogensulfite, and in alkaline solution to give the sulfide and sulfite:

$$2\,Na_2S_2O_4 \xrightarrow{H^+} Na_2S_2O_3 + Na_2S_2O_5$$

$$3\,Na_2S_2O_4 + 6\,NaOH \longrightarrow Na_2S + 5\,Na_2SO_3 + 3\,H_2O$$

The decomposition in alkaline solution is accelerated by thiosulfates and polysulfides. On addition of strong acids the dithionite solution first becomes yellow-red, and after a short time complete decomposition occurs with precipitation of sulfur. The dithionite can be recovered if the solution is rapidly neutralized before the sulfur precipitates. Weak alkalis (pH 8 – 13) stabilize dithionite solutions, which can then be kept for weeks below 10 °C with the exclusion of air. In the presence of air the dissolved dithionite is converted rapidly into sulfate and sulfite at room temperature, with or without stabilizer.

The industrial applications of sodium dithionite are determined by its strong reducing properties, due to the S – S bond and the oxidation state of the sulfur in the compound.

With relatively strong oxidizing agents, such as potassium permanganate and iodine, sulfate is formed; with weaker ones, such as vat dyes, sulfite is formed. With MnO_2, dithionate can be formed.

3.3. Production

All processes for the production of dithionite start with the reduction of sulfurous acid, which can either be present in the free form or as hydrogensulfite. The production processes with zinc dust, sodium amalgam, sodium formate, sodium borohydride, and electric current as the reducing agent are important industrially.

Zinc-Dust Process. Some important producers still use the zinc-dust process, which was developed by BASF. The basic reactions are:

$$Zn + 2\,SO_2 \longrightarrow ZnS_2O_4$$

$$ZnS_2O_4 + 2\,NaOH \longrightarrow Zn(OH)_2 + Na_2S_2O_4$$

An aqueous slurry of zinc dust is treated in a stirred reactor with cooling at ca. 40 °C with liquid or gaseous sulfur dioxide to give zinc dithionite. After completion of the reaction the solution is passed through a filter press to remove unreacted zinc dust and impurities from the zinc.

The zinc is then precipitated from the zinc dithionite by adding sodium carbonate or sodium hydroxide in stirred vessels. The zinc carbonate or hydroxide is removed in filter presses. Anhydrous sodium dithionite is precipitated from the clarified sodium dithionite solution by concentration under vacuum and addition of sodium chloride at > 60 °C. It is filtered, washed with methanol, and dried at 90 – 100 °C.

Besides the evaporation process the salting out process, which was more widely used previously, is still known. In this process the dithionite is obtained from the solution by the addition of sodium chloride and methanol.

The zinc carbonate or hydroxide formed as side products can be further processed to give zinc salts or zinc oxide.

Amalgam Process. In the amalgam process, sodium hydrogensulfite is reduced to sodium dithionite in aqueous solution in a cooled, stirred vessel using the sodium amalgam of a chloralkali electrolysis cell. The sodium-free mercury is returned to the electrolysis cell where it is recharged with sodium. During reaction of the amalgam with the hydrogensulfite solution a pH of 5 – 6 must be maintained. The product is obtained by precipitation with salts or methanol or both.

Formate Process [28]. Sodium formate, dissolved in 80 % aqueous methanol, is charged to a stirred vessel. At a pressure of 2 – 3 bar sulfur dioxide and sodium hydroxide are introduced into this solution such that a pH of 4 – 5 is maintained. The reaction can be described by the following equation:

$$HCOONa + 2\,SO_2 + NaOH \longrightarrow Na_2S_2O_4 + CO_2 + H_2O$$

Under the above conditions anhydrous sodium dithionite precipitates as fine crystals. It is filtered, washed with methanol, and dried.

Sodium Borohydride Process. Sodium borohydride is stable in strong aqueous alkali and can be used in this form for the production of sodium dithionite by adding SO_2 and sodium hydroxide:

$$NaBH_4 + 8\,NaOH + 8\,SO_2 \longrightarrow 4\,Na_2S_2O_4 + NaBO_2 + 6\,H_2O$$

Electrolytic Process [29]. The electrolytic process, developed by BASF and by Olin, is used in only one small plant.

In a bipolar electrolysis cell, with the cathode and anode spaces separated by a semipermeable membrane, disulfite ions are reduced to dithionite at the cathode at pH 5 – 6. At the anode chloride ions, for example, are oxidized to chlorine. For charge equalization sodium ions pass through the membrane from the anode space to the cathode space. This process gives a dithionite solution which can be further processed as in the amalgam process.

3.4. Quality Specifications and Analysis [30]

Commercial sodium dithionite generally has a purity of ca. 88 %. It contains ca. 3 % of each of the following: sodium disulfite, sodium sulfite, sodium sulfate, and sodium carbonate. The latter stabilizes the $Na_2S_2O_4$. The total heavy metal content is generally < 20 ppm. The product from the zinc-dust process has a zinc content of up to 300 ppm.

The sodium dithionite content can most readily be determined iodometrically. It is dissolved in a neutral formaldehyde solution in a standard flask. The dithionite, which is sensitive to oxidation, reacts immediately on dissolving to give the more stable sodium hydroxymethanesulfinate, which can be titrated.

$$Na_2S_2O_4 + 2\,CH_2O + H_2O \longrightarrow HOCH_2SO_2Na + HOCH_2SO_3Na$$

$$HOCH_2SO_2Na + 2\,I_2 + 2\,H_2O \longrightarrow NaHSO_4 + 4\,HI + CH_2O$$

However, this method of analysis does not differentiate between dithionite and any thiosulfate which may be present. Since no acid is formed in the iodometric oxidation of thiosulfate, but is formed in the dithionite titration, the proportion of dithionite can be determined by subsequent titration of the solution with alkali.

3.5. Trade Names and Uses

Sodium dithionite is sold as the 88 % product, for example, under the names Hydrosulfit (BASF, Brüggemann, Germany; Prayon, Belgium; Hoechst-Celanese, USA; Hoechst-UK, UK, etc.), Blankit (BASF), Albite A (Idrosol, Italy), and Konite (Akzo, Holland). Hydrosulfit mixtures are sold, for example, under the names Blankit (with index, BASF), Blancolen (Brüggemann, Germany), Albite LA (Idrosol, Italy), Konite TP (Akzo, Holland), Zepar (Du Pont), Burmol (BASF), Arostit (Sandoz).

All uses of sodium dithionite are based on its reducing properties. It is used predominantly in the textile industry as a dyeing and printing auxiliary and as a bleaching agent in the textile and paper industries.

In dyeing and printing, sodium dithionite is used to convert insoluble vat dyes to the soluble leuco form. High-purity sodium dithionite (e.g., Blankit) is used to bleach wool, cotton, silk, bristle, straw, horsehair, coconut fiber, raffia, soaps, glues, clay, sand, bauxite, and in some countries for bleaching sugar, syrup, fruit, edible oils, edible fats, and gelatin.

For special applications in the paper or textile industries complexing agents such as trilons or phosphates, or also optical brighteners are added to dithionite-containing products.

The reducing action of sodium dithionite is also used in preparative and analytical chemistry. It can reduce azo, diazo, nitro, nitroso, and carbonyl groups.

3.6. Safety and Environmental Aspects; Storage and Transport

Above a certain dithionite concentration, mixtures in powder form decompose if subjected to prolonged exposure to high temperatures or

come into contact with water. In the case of very finely divided products this decomposition can already occur at 80 °C. Product that is decomposing must be covered immediately with dry sand or powder extinguisher, or dissolved by shovelling into large quantities of water. If sodium dithionite packed in iron drums ignites, the SO_2 gas produced must be allowed to escape by opening the container or drilling holes in the wall. The contents of the container are destroyed by throwing them into large quantities of water. The aqueous solution thus formed must be treated as it contains reducing agent and must be slowly introduced into an appropriate wastewater-treatment plant. Gloves and respiratory protection must be worn while extinguishing fires.

Dithionite is classified in the German water hazard class 1 as posing a slight hazard to water.

The wastewater from all production processes contains approximately equal quantities of reducing agent, which must be removed in a wastewater-treatment plant. The CO_2 formed in the formate process (Section 3.3) must be freed from SO_2, methanol, and thiols before being released into the atmosphere.

Commercial sodium dithionite (e.g., Hydrosulfit and various product mixtures, which contain Hydrosulfit) are spontaneously combustible hazardous goods (Class 4.2, UN no. 1384), and are therefore subject to the corresponding transport regulations [31–35].

Because of the danger of spontaneous ignition sodium dithionite and its mixtures must be stored dry and in a cool place. Storage or transport together with sodium nitrite, sodium nitrate, and ammonium nitrate is forbidden. Transport containers must always be kept closed. Product should only be removed in a dry area using dry equipment.

3.7. Economic Aspects

World consumption of sodium dithionite is ca. 300 000 t/a, corresponding to ca. 60 % of production capacity in 1990. The zinc dust process accounts for ca. 35 % of the capacity, the formate process 40 %, the amalgam process 15 %, and the sodium borohydride process 10 %.

3.8. Toxicology [36]

The LD_{50} (rat, oral) is ca. 2500 mg/kg. In the rabbit the product has no irritant effect on the skin, but has an irritant effect on the mucous membrane (rabbit's eye). Therefore, in an emergency or as first aid measures it is sufficient to wash the skin thoroughly with water and to rinse the eyes for 10 min. with running water. An eye specialist should then be consulted.

The 48-h LC_{50} in golden orfe is 10 – 100 mg/L.

1. Sulfones

1.1. Physical and Chemical Properties

Sulfones are described by the following general structural formula, in which the groups R^1 and R^2 can be hydrocarbon substituents, including cyclic ones, of any combination:

Typical sulfones are colorless and odorless in the pure state and are very stable both thermally and chemically. They are protonated only by the strongest acid systems. Unlike sulfoxides, sulfones form relatively weak hydrogen bonds.

The presence of a sulfonyl group in the molecule is shown by strong absorptions at 1300 – 1320 cm^{-1} and 1140 – 1160 cm^{-1} in the IR spectrum. Physical properties of industrially important sulfones are listed in Table 1.

1.2. Synthesis [1, pp. 223, 1129], [2], [3, p. 171]

1.2.1. Oxidation of Thioethers (Sulfides)

Sulfones are generally synthesized by oxidation of sulfides via sulfoxides as intermediates. A common oxidizing agent in the laboratory is hydrogen peroxide in acetic acid. It is also often used in industry, but requires reaction temperatures of 70 °C up to reflux in many cases [4], [5]. In the presence of various metal catalysts, oxidation with hydrogen peroxide proceeds under milder conditions. Thus, β-hydroxy sulfides can be oxidized selectively and in good yield to the corresponding sulfones by using titanium, vanadium, molybdenum, or tungsten salts [6], as well as selenium dioxide [7], as catalysts. A very effective oxidizing agent, which gives high-purity products in high yield, is *m*-chloroperbenzoic acid (MCPBA). This reagent can often be used if the molecule contains other sensitive groups,

$C_6H_5-SO_2-CH_2-OH$	57–60	$C_7H_8O_3S$ (172.20)
$4\text{-}CH_3-C_6H_4-SO_2-CH(OH)-(CH_2)_2-CH_3$	78	$C_{11}H_{16}O_3S$ (228.31)
$CH_3-(CH_2)_{11}-SO_2-CH_2-OH$	64–66	$C_{13}H_{28}O_3S$ (264.43)

as in many pharmaceutically active substances [8]. Alkyl thiocyanates are converted to sulfonyl cyanides by MCPBA [9]

$$R-SCN \xrightarrow{MCPBA} R-SO_2-CN$$

Other oxidizing agents used include potassium permanganate [10], sodium perborate [11], and dimethyldioxirane [12]. An extremely simple, rapid process is sulfide oxidation with periodic acid in the presence of ruthenium tetroxide as catalyst. This reaction is carried out in a two-phase solvent mixture and is, therefore, also suitable for the synthesis of water-soluble sulfones [13]. A related method using osmium tetroxide in the presence of a tertiary amine *N*-oxide gives good yields [14]. In industrial processes, gaseous chlorine is also used as the oxidizing agent (see, for example [15]). The potassium peroxomonosulfate complex Oxone has also gained importance [16]. With this reagent, allyl sulfoxides, for example, can be converted into the corresponding sulfones [17]. In the presence of wet clays such as kaolin or montmorillonite, the oxidation of various sulfides in dichloromethane gives the sulfone almost quantitatively [18].

Oxidation of Phenyl Vinyl Sulfide with H_2O_2 in Glacial Acetic Acid [4]. To a solution of 19.7 g (0.145 mol) of phenyl vinyl sulfide in 70 mL of glacial acetic acid, 56 mL (0.5 mol) of 30 % hydrogen peroxide is added dropwise in such a way that the reaction temperature becomes 70 °C. The reaction mixture is subsequently heated for 20 min under reflux. After cooling, 150 mL of diethylether and 200 mL of water are added, and the organic phase is separated. The organic phase is subsequently washed with water (50 mL) and sodium chloride solution (50 mL) and evaporated, giving 18 – 19 g (74 – 78 %) of phenyl vinyl sulfone as a colorless solid, *mp* 64 – 65 °C.

Oxidation of Sulfides with Oxone in the Presence of Wet Montmorillonite [18]. Commercial clay (montmorillonite or kaolin; 10 g) is treated with 2 g of distilled water in eight portions. After each addition the mixture is shaken vigorously for several minutes, until a loose powder is formed. Then 1.2 g of this catalyst is suspended in 6 mL of dichloromethane (7 mL for the kaolin catalyst) and treated with Oxone (2.5 equivalents based on the sulfide). After addition of 1 mmol sulfide the reaction vessel is purged with argon, closed, and stirred for 2 h at room temperature. After filtration of the catalyst on a glass frit, washing with ca. 100 mL of dichloromethane, and evaporation of the solvent, the pure sulfone (> 98 % purity) is obtained almost quantitatively.

A particularly simple and rapid process allows the synthesis of sulfonyl-substituted propanones on a large scale [19]. Here, chloroacetone is reacted with various sulfides. The intermediate β-keto sulfide is not isolated but is oxidized directly with Oxone to the sulfone.

$$CH_3-CO-CH_2Cl + R-SH \xrightarrow[MeOH]{NaOH} CH_3-CO-CH_2-S-R \xrightarrow[H_2O]{Oxone} CH_3-CO-CH_2-SO_2-R$$

1.2.2. Alkylation of Sulfinic Acid Derivatives

Alkylation of the ambidentate sulfinate ion with soft alkylating agents, such as alkyl halides, is a widely used method for synthesis of sulfones:

$$R^1-SO_2^-Na^+ + R^2-X \longrightarrow R^1-SO_2-R^2$$

Aryl sulfones, in particular, in which the second sulfonyl substituent can be an alkyl [20], an alkynyl [21], a β-keto [22], or an allyl [23] group, can be produced by this process. These reactions are catalyzed, for example, by copper(I) bromide [24], phase-transfer catalysts [20], [21], [25], or ultrasound [26].

A related reaction is that of arylsulfonyl chlorides with alkyl iodides or benzyl chlorides in the presence of telluride. The reaction is based on a reactivity inversion, where the original electrophilic sulfonyl group is converted to the nucleophilic sulfinate ion by electron transfer from the telluride ion [27]:

$$Ar-SO_2Cl \xrightarrow{Te^{2-}} [Ar-SO_2^-] \xrightarrow{R-X} Ar-SO_2-R$$

Substituted vinyl and allyl sulfones are obtained in good yield by palladium-catalyzed coupling of arylsulfonyl chlorides with organotin compounds [28].

$$Ar-SO_2Cl + Bu_3Sn-CH=CH-R \xrightarrow{(Ph_3P)_4Pd} Ar-SO_2-CH=CH-R$$

The sulfonylation of various organometallic reagents with arylsulfonyl fluorides is a one-step sulfone synthesis, which gives alkyl, trimethylsilylmethyl, and allyl sulfones in good yield [29]. Cycloalkenes can be converted particularly easily into the corresponding vinyl sulfones by reaction with tetrabutylammonium sulfinate [30].

1.2.3. Addition of Sulfinic Acid Derivatives to Multiple Bonds

Isolated double bonds do not generally react with sulfinic acids or their salts to give sulfones. Iodosulfonylation and sulfonylmercuration, which both take place regioselectively [31], are exceptions. The adducts formed initially are converted by dehydrohalogenation or demercuration into the corresponding vinyl sulfones (see Figure 1).

Figure 1.

Conjugated dienes [32] and α,β-unsaturated carbonyl compounds [33] can also be converted regioselectively into unsaturated sulfones by using iodosulfonylation.

The addition of sulfinic acids to polarized double or triple bonds is an excellent method of synthesizing sulfones [34]. A large number of olefins, such as vinyl aldehydes [35] and ketones [36], nitroolefins [37], acrylic acid derivatives [38], vinyl sulfones [39], quinones [40], and quinonimines [41] have been used successfully as acceptor compounds.

Sulfinic acid also adds readily to sulfonyl-substituted allenes and acetylenes to give disulfonyl derivatives [42].

Unlike sulfinic acids, the addition of sulfonyl halides to unsaturated C–C systems is a radical reaction in which mixtures of isomers can be formed. To suppress competing polymerization reactions, the addition is carried out in the presence of copper(I) or copper(II) salts. The β-halo sulfones formed initially can be converted into vinyl sulfones by elimination of hydrogen halide [43].

1.2.4. Rearrangement of Sulfinates

Sulfinates rearrange to sulfones under various conditions. Acids [44], tertiary amines [45], or palladium(0) complexes [46] are examples of suitable catalysts. Allyl-substituted sulfinic acid esters can also be isomerized thermally [46], [47].

1.2.5. Sulfones from Sulfonyl Carbanions

α-Sulfonyl carbanions are formed from sulfones containing α-hydrogens by the action of bases, such as Grignard reagents, alkali-metal amides, sodium hydride, or butyllithium. These carbanions can be converted into a variety of new sulfones by alkylation, acylation, or addition to unsaturated systems.

Treatment of α-sulfonyl carbanions with acid chlorides [48] or esters [49] gives β-keto sulfones, which can rearrange with allyl bromide to give α-allyl-substituted β-keto sulfones [50].

The Knoevenagel condensation of aryl sulfones with aldehydes or ketones is also frequently used. The intermediate products eliminate water to form vinyl sulfones [51] (see Figure 2).

The Knoevenagel condensation, with subsequent allyl sulfoxide – sulfenic acid ester rearrangement, is of synthetic importance in the production of γ-hydroxy-α,β-unsaturated sulfones. Here piperidine is used as the base [52] (see Figure 3).

Figure 2.

Figure 3.

1.2.6. Addition of Sulfur Dioxide

By addition of sulfur dioxide to aryldiazonium salts, aryl sulfonyl radicals are formed, which can react with olefins to give alkyl aryl sulfones [53].

1,3-Dienes undergo stereoselective cycloaddition with sulfur dioxide to give sulfolenes. This reaction is reversible [54].

1.3. Reactions

Reductive Elimination of the Sulfonyl Group. Reductive elimination of the sulfonyl group is of great synthetic importance because sulfones are used as intermediates in many syntheses. Alkali metals in ammonia or low molar

mass amines [55], sodium amalgam [56], and aluminum amalgam [57] have been described as reducing agents. Sulfur dioxide is eliminated from unsaturated, cyclic sulfones by potassium dispersed with ultrasound [58].

The simultaneous reduction and desulfonylation of α-alkylidene β-keto sulfones is effected under mild conditions by using sodium hydrogentelluride [59].

The sulfonyl group can be eliminated photochemically from β-keto sulfones by using a β-keto ester in the presence of a ruthenium(II) salt, so that many other functional groups are not attacked [60].

Elimination of Sulfinate. The base-catalyzed elimination of organic sulfinate groups from sulfones is often used preparatively. Arylsulfonyl [61] and, in particular, trifluoromethanesulfonyl groups are good leaving groups [62]:

Ramberg–Bäcklund Reaction. Bases effect the elimination of sulfur dioxide from α-halo sulfones with α-hydrogens via an episulfone intermediate, to give olefins [63].

Smiles and Truce–Smiles Rearrangement. Diaryl and aralkyl sulfones undergo base-catalyzed rearrangement to form sulfinic acids [64]. In the *Smiles rearrangement* the migrating aryl group must be activated by an electron-withdrawing group.

In the related *Truce–Smiles rearrangement* a nonactivated aryl or tertiary alkyl group migrates to a carbanion formed by lithiation of an *o*-methyl group [65].

1.4. Industrial Uses

Unsaturated sulfones can be used as intermediates for pharmaceuticals and pesticides and for modification of polymers [66]. Many reactive dyes also contain unsaturated sulfonyl groups, (e.g., see [67]). The possible uses of sulfones described below are taken from the extensive patent literature. For uses of sulfolane, see → Benzene, Chap. 6.3.; → Gas Production.

Uses in Crop Protection. 1,1-Diiodomethyl sulfone [68], heterocyclic sulfones [69], and α-sulfonyloximes [70] have been described as *plant fungicides*. Certain sulfones are effective *herbicides* [71]. Others act as *insecticides* and *acaricides* [72].

Pharmaceutical Uses. Dihydropyridine sulfone derivatives are *calcium antagonists*, which are said to have a longer period of activity and fewer side effects than nifedipine [73]. Alkylsulfonyl-substituted steroid pyrazoles and thiazoles exhibit *antiandrogenic activity* [74].

Sulfonylnitromethane derivatives are aldose reductase inhibitors and can be used for the treatment of certain secondary effects of *diabetes* and *galactosemia* [75]. A range of sulfonyl-substituted benzazepines and imidazoles have

been patented as agents for the treatment of *gastrointestinal disorders* [76]. Fluoro sulfones are said to be very effective leukotriene antagonists with *antiallergic* and *anti-inflammatory activity* [77]. Aryl- or heteroaryl-substituted sulfones exhibit activity against *picornaviruses* [5] and *retroviruses* [78]. Sulfonylcyclopentenones are *antitumor agents* and promote *bone formation* [79].

Others. Piperidinyl sulfones are used as light stabilizers in polymers, particularly polyolefins [80]. Certain heterocyclic sulfones can be used as*corrosion protection agents* for metals [81]. Sulfones are used as hardeners [82] and couplers [83] in *photographic materials*. Diazodisulfones can be used in the production of *semiconductors* and as photosensitive reagents for *printing plate materials* [84]. Certain fluorinated sulfones have *nonlinear optical properties* [85]. Sulfone percarboxylic acids are *bleaching agents* with little damaging effect on colors and good storage stability [86]. *Fabric softeners* contain esters or ethers of thiodiglycol sulfones [87].

2. Sulfoxides

2.1. Physical and Chemical Properties

Sulfoxides are colorless, hygroscopic liquids or solids. They dissolve readily in protic solvents to form strong hydrogen bonds. Because of the polar nature of the S−O bond, sulfoxides form adducts with salts of most metals.

Because of the pyramidal structure of sulfoxides, unsymmetrically substituted compounds of this series form enantiomers, with the sulfur atom as the chiral center.

In sulfoxides, sulfur has the intermediate oxidation state of +4. Sulfoxides can therefore be reduced to form sulfides (thioethers) and oxidized to form sulfones by reversible redox reactions.

Physical properties of important sulfoxides are listed in Table 2.

2.2. Synthesis

2.2.1. Oxidation of Sulfides [1, pp. 207, 665], [2], [3, p. 121], [88], [89]

The oldest and most frequently used method for the production of sulfoxides is by oxidation of sulfides. Since further oxidation to the corresponding sulfones can occur, a range of selective reagents and methods has been developed. Oxidation with hydrogen peroxide, which has long been known, can be carried out in the presence of various catalysts. Acids, such as acetic [90], [91], perchloric [92], and sulfuric acids [93], [94] are suitable. A more recent industrial process uses 50 % sulfuric acid and an organic acid, such as formic or acetic acid, in a 1 : 1 ratio as the catalyst [93]. Similarly, sterically hindered sulfides can be oxidized selectively and in high yield with hydrogen peroxide in the presence of a catalyst mixture of sulfuric acid and a secondary or tertiary alcohol [94]. Other suitable catalysts are titanium trichloride [95], selenium dioxide [96], tellurium dioxide [97], and vanadium pentoxide [98], which can act simultaneously as an indicator of excess hydrogen peroxide. Good yields of sulfoxide are obtained by using the complex from urea and hydrogen peroxide (UHP complex) together with half an equivalent of phthalic anhydride [99]. The use of organic peroxides, such as cyclohexyl or *tert*-butyl hydroperoxide has also been known for a long time [100]. Sulfide oxidation takes place quantitatively at −78 °C using 2-methoxy-2-hydroperoxypropane produced in situ from 2,3-dimethyl-2-butene and ozone [101]. Among the organic peroxycarboxylic acids, peracetic [102], perbenzoic [103], and monoperoxyphthalic acids [104], in particular, are effective oxidizing agents. One of the best selective oxidizing agents is *m*-chloroperoxybenzoic acid, which not only gives sulfone-free sulfoxides [105], but also reacts with a broad range of substrates [106] including unstable unsaturated thioethers [4], multifunctional heterocyclic thioesters [107], thioacetals [108], disulfides [109], and penicillins [110].

Table 2. Physical data and molecular formulas for some industrially important sulfoxides

Sulfoxide	*mp*, °C (*bp*, °C/kPa)	Molecular formula (molecular mass)
$C_6H_5-CH_2-SO-CH_2-C_6H_5$	134–135	$C_{14}H_{14}OS$ (230.33)
$C_6H_5-SO-CH_3$	33–34	C_7H_8OS (140.21)
$C_6H_5-SO-C_6H_5$	69–71	$C_{12}H_{10}OS$ (202.28)
$C_6H_5-SO-CH_2-COOH$	118–119	$C_8H_8O_3S$ (184.21)
$CH_3-CH_2-SO-CH_2-CH_3$	(45–47/0.015)	$C_4H_{10}OS$ (106.19)
	67–68	$C_5H_{10}OS$ (118.20)
	109–110	$C_5H_8O_2S$ (132.18)
	91–92	$C_7H_{12}O_2S$ (160.24)
$C_6H_5-SO-CH_2-CH_3$	(68–70/0.005)	$C_8H_{10}OS$ (154.23)
$CH_3-(CH_2)_3-SO-(CH_2)_3-CH_3$	(105/0.3)	$C_8H_{18}OS$ (162.30)
$4\text{-}H_3C-C_6H_4-SO-CH_3$	38–39	$C_8H_{10}OS$ (154.23)
$C_6H_5-CH_2-SO-CH_2-CH_3$	51–52	$C_9H_{12}OS$ (168.26)
$C_6H_5-SO-CH_2-C_6H_5$	122–123	$C_{13}H_{12}OS$ (216.30)
$CH_3-(CH_2)_2-SO-(CH_2)_2-CH_3$	(73–75/0.1)	$C_6H_{14}OS$ (134.24)
$C_6H_5-CH_2-SO-CH_3$	53–54	$C_8H_{10}OS$ (154.23)
$C_6H_5-SO-CH=CH_2$	(105–110/0.15)	C_8H_8OS (152.22)
$4\text{-}H_3CO-C_6H_4-SO-CH_3$		$C_8H_{10}O_2S$ (170.23)
$C_6H_5-SO-CH_2-CH=CH_2$		$C_9H_{10}OS$ (166.24)
$C_6H_5-CO-CH_2-SO-C_6H_4-4\text{-}CH_3$	83– 84	$C_{15}H_{14}O_2S$ (258.34)
$4\text{-}CH_3-C_6H_4-SO_2-CH_2-SO-C_6H_4-4\text{-}CH_3$	117–118	$C_{15}H_{16}O_3S_2$ (308.42)

The longest-known oxidizing agent, used for sulfide oxidation as early as 1865, is nitric acid [111]. In the presence of gold (III) salts and by phase-transfer catalysis, oxidation with aqueous nitric acid in nitromethane is selective; oxidizable groups such as vinyl, tertiary amino, hydroxy, and diol groups are not attacked [112]. Very good yields of sulfoxide are also obtained with acetyl and benzoyl nitrates [113], and with the inorganic oxidants thallium(III) nitrate [114] and ceric ammonium nitrate (CAN). Oxidation with CAN alone is limited to diaryl sulfides, since in the presence of an α-hydrogen in the substrate molecule, the sulfoxide formed undergoes a Pummerer rearrangement under reaction conditions [115]. When CAN oxidation is carried out with sodium bromate as a co-oxidizing agent [116] or by phase-transfer catalysis [117], dialkyl and aryl alkyl sulfides can also be oxidized selectively. One of the most frequently used methods for effecting the sulfide–sulfoxide transformation is oxidation with sodium metaperiodate in aqueous methanol at 0 °C [118]. Modified processes employ sodium metaperiodate on an alumina carrier [119] or water-insoluble tetrabutylammoni-

um metaperiodate in boiling chloroform [120]. Iodosobenzene [121] and *o*-iodosylbenzoic acid [122] are also effective oxidizing agents. Selective oxidation with halogen compounds, such as sodium bromite [123], benzyltrimethylammonium tribromide [124], and particularly sodium hypochlorite has been described. The latter can be used in alkaline media at pH > 10 for the production of pharmacologically active compounds [125].

In addition to sulfones, sulfoxides are also obtained by reaction of sulfides with Oxone [16]. In the presence of wet alumina, phenyl alkyl sulfides are converted to either sulfone-free sulfoxides or sulfones, depending on the quantity of Oxone used [126]. Diastereoselective oxidation with Oxone has also been described [127].

Synthesis of 4-Chlorobenzyl-*N,N*-Diethylcarbamoyl Sulfoxide [94]

10 mol (2.575 kg) 4-chlorobenzyl-*N*,*N*-diethylthiocarbamate are dissolved in 1.5 L of toluene and treated with 0.4 L of formic acid and 0.4 L of 50 % sulfuric acid. Then 1.07 kg of 35 % hydrogen peroxide (11 mol) is added dropwise with stirring and ice- cooling in such a way that the temperature of the reaction mixture does not exceed that of the surroundings. After the mixture has been stirred for 4 h at room temperature, the organic phase is separated and neutralized with 20 % aqueous NaOH. The toluene phase is washed with water and evaporated to give the sulfoxide in 95 % yield (purity 95 %).

Synthesis of Phenyl Vinyl Sulfoxide [4]

A solution of 20 g (0.147 mol) phenyl vinyl sulfide in 250 mL of dichloromethane, is cooled to − 78 °C, and a solution of 25.4 g (1.0 equivalent) of *m*- chloroperoxybenzoic acid in 200 mL of dichloromethane is added dropwise with stirring over 30 min. The reaction mixture is then warmed for 1 h in a water bath at 30 °C and poured into 300 mL of saturated hydrogencarbonate solution. The organic phase is separated, and the aqueous phase is extracted with 3×250 mL of dichloromethane. The combined organic phases are dried over magnesium sulfate, and after evaporation of the solvent, the residue is distilled. About 15 – 16 g (68 – 70 %) of the sulfoxide is obtained as a colorless liquid, *bp* 98 °C (80 Pa).

2.2.2. Reaction of Sulfur Dioxide with Aromatics

Simple aromatic compounds can be converted into the corresponding sulfoxides in good yield with sulfur dioxide and an equimolar quantity of Magic Acid ($FSO_3H \cdot SbF_5$). Unsymmetrical sulfoxides are also accessible by this route [128].

2.2.3. Sulfoxides from Sulfinates

Reaction of sulfinates with organometallic compounds, such as Grignard reagents and organocopper or organolithium reagents, is important for the production of optically active sulfoxides.

An extension of this reaction is the Claisen condensation of enolate anions with methyl arylsulfinates, giving α-keto sulfoxides [129].

2.2.4. α,β-Unsaturated Sulfoxides

A range of vinyl sulfoxides is accessible through trapping reactions of thermally produced sulfenic acids with alkynes [130].

2.2.5. Optically Active Sulfoxides

Chiral sulfoxides, which play an important role in asymmetric synthesis, are produced by asymmetric synthesis, optical and kinetic separation of enantiomers, and stereospecific synthesis; for reviews, see [3], [131].

2.3. Reactions

2.3.1. Reactions of α-Sulfinyl Carbanions

Strong bases, such as butyllithium, sodium hydride, or lithium dialkylamide, deprotonate sulfoxides with α-hydrogens to give α-sulfinyl carbanions. The latter react stereoselectively with organic electrophiles to form C–C bonds [1], [2, p. 583].

Subsequent reactions consist of reductive cleavage of the sulfinyl group to a ketone and elimination with the formation of a double bond. These processes have been used for the synthesis of various ketones and carboxylic acids [132].

For α-halogenation of sulfoxides, which also proceeds via sulfinyl carbanions, various reagents have been described [1], [3].

Halogenation with *N*-halosuccinimides [133] and chlorination with *N*-,*N*-dichloro-*p*-toluenesulfonamide [134] give good yields.

2.3.2. Reactions with Grignard Reagents

Ligand exchange reactions between heterocyclic sulfoxides and Grignard reagents are used for production of the corresponding heterocyclic Grignard reagents. Subsequent reaction of these organometallic derivatives with carbonyl compounds provides a route to new heterocyclic compounds [135], [136].

A variant of this reaction is ligand coupling. The heterocyclic Grignard compound (**2**) formed initially reacts with the educt sulfoxide (**1**) to give the coupling product **3** [137].

This reaction is used mainly for the synthesis of bisaryls [138], [139].

2.3.3. Pummerer Rearrangement

In the Pummerer rearrangement, sulfoxides having at least one α-hydrogen are treated with acids or strong electrophiles such as carboxylic acid anhydrides or chlorides to form α-substituted sulfides as the primary products.

The Pummerer rearrangement is used widely in synthesis [1], [3]. For example, α-dicarbonyl compounds are formed from β-keto sulfoxides on acidic workup.

Cycloalkyl phenyl sulfoxides are converted into vinyl sulfides under conditions of the Pummerer rearrangement [140].

2.3.4. Oxidation and Reduction

Oxidation of sulfoxides to sulfones not only is a frequently occurring side reaction in the production of sulfoxides, but is also used for the synthesis of sulfones (see Section 2.2.1).

Reduction of sulfoxides to sulfides is achieved with hydrogen in ethanol on Pd–C catalysts [141] or selectively with dichloroborane [142] even in the presence of acid chloride, ester, nitrile, or nitro groups. Deoxygenation of sulfoxides with zinc – dichlorodimethylsilane under very mild conditions [143] and with polystyryldiphenylphosphine [144] has also been described. These reactions have no effect on a wide variety of functional groups and permit a cleaner product isolation.

2.4. Uses

Many sulfoxides are used as intermediates in the production of pharmaceuticals, plant protection agents, and other physiologically active substances.

Sulfoxides also play an important role in the synthesis of optically active substances. A selection of patents on the use of sulfoxides is given below.

Crop Protection and Veterinary Drugs
Insecticides and acaricides [145].
Bactericides and fungicides [146].
Plant growth regulators [147].
Anthelmintics in veterinary medicine [148].

Pharmaceuticals
Agents for treating gastrointestinal disorders [149].
Enantiomerically pure sulfoxides as cardiovascular medicines [150].
Sulfoxide derivatives of 5-thiaprostaglandin E_1 act as vasodilators and inhibit thrombocyte aggregation [151].
Thiocarbamoylsulfoxide derivatives exhibit antihypertensive action [152].
Imidazolyl sulfoxides are anti-inflammatory and are also said to be suitable for treating asthma and skin diseases such as psoriasis [153].
Trichlororuthenium complexes with a sulfoxide group have antitumor activity [154].
Agents for treating allergic reactions, particularly asthma [155].
Methionine sulfoxide lowers the liver toxicity of acetaminophen in humans [156].
Tetrahydrothiophen-1-oxide and its derivatives are inhibitors of alcohol dehydrogenase and therefore act as antidotes for alcohol poisoning [157].
Various sulfoxides are enzyme inhibitors [158].
Thiocarbamate sulfoxides have been described as agents for combating alcohol addiction [159].
Agents for treating sun-damaged skin [160].
Sulfoxides support the percutaneous absorption of a range of pharmaceuticals [161].

Others
Bis(2-hydroxyethyl) sulfoxide is used to treat oily hair [162].
Sulfoxides act as stabilizers for polymers and lubricating agents against heat, light, and oxygen [163].
Polyalkoxylated thioglycol sulfoxides are used as fabric softeners [164].
Use in refrigerating liquids for refrigerators and air-conditioning equipment [165].
Coupling agents in silver halide color films [166].

2.5. Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO) is a colorless, odorless, strongly hygroscopic liquid. It is readily miscible with water and other protic solvents such as alcohols. This property can be attributed to the formation of strong hydrogen bonds between the polarized S–O bond and water molecules. The strong polarity of the S–O bond, with a partial negative charge on oxygen (see formula) is shown by the high dipole moment (4.3 ± 0.1 D at 20 °C) and basicity ($pK_B = -2.7$) of dimethyl sulfoxide. Pure DMSO forms chain-like polymeric association complexes at room temperature. This gives rise to considerably higher melting and boiling points compared to dimethyl sulfide (see Table 3).

Table 3. Comparison of physical properties of dimethyl sulfide and dimethyl sulfoxide

	Dimethyl sulfide	Dimethyl sulfoxide
mp, °C	−98	18.5
bp, °C	38	189
d, g/mL	0.846	1.101

2.5.1. Production

In principle, DMSO can be produced by oxidation of dimethyl sulfide as described in Section 2.3.1. These methods are, however, often suitable only for small quantities. In industry, DMSO is produced by catalytic oxidation of dimethyl sulfide with oxygen or by oxidation with nitrogen dioxide [167]. The oxidation of dimethyl sulfide with oxygen at 7.2 MPa and 105 °C gives good yields of DMSO [168].

2.5.2. Uses

Dimethyl sulfoxide is an excellent solvent [169] that is widely used for reactions in modern chemistry. Because of its high polarity and good solvation of cations, DMSO dissolves not only a large number of organic compounds, but also many metal salts, particularly those of alkali and alkaline-earth metals. DMSO is also a good solvent for many polymers.

A range of different pharmacological properties and effects have been described for DMSO [170]. For example, it increases the capacity of the skin to absorb drugs, and exhibits both analgesic and bacteriostatic activity. It can be used for the treatment of infection by retroviruses [171] and as an anti-inflammatory agent. Furthermore, DMSO has been described as a preservative and cryo-protective agent for organ and tissue transplants [172].

In plant protection, DMSO can be used to ward off mammals (e.g., deer [173]) and as a growth stimulant [174].

2.5.3. Reactions

The so-called dimsyl anion, formed on treatment of dimethyl sulfoxide with base, can react further like other sulfinyl carbanions (see Section 2.3.1).

Cyclic ketones react with DMSO in the presence of KOH to give 2-methylenecycloalkanols [175].

The methylation of various aromatic systems by the dimsyl anion is also of interest [176].

3. Toxicology

3.1. Sulfones [177–181]

The toxicity of sulfones is generally low. The sulfonyl group is relatively stable metabolically.

However, for some compounds, enzymatic reduction to the sulfide has been discussed. For the solvent *sulfolane* (tetramethylene sulfone), on oral administration to rats, an average lethal dose of 1.8 – 2.5 g/kg has been found. Various mammals show neurotoxic symptoms after oral administration, injection, inhalation, or dermal absorption of sulfolane. No information is available on the carcinogenic or teratogenic activity of sulfolane. *p-Chlorophenyl phenyl sulfone*, used as an insecticide, is a skin irritant; in animal experiments, liver and kidney damage occurs. For *2,4,5,4′-tetrachlorodiphenyl sulfone* (tetradifon, an acaricide), very low toxicity has been found in animal experiments.

3.2. Dimethyl Sulfoxide [178], [181–184]

Dimethyl sulfoxide has very low *acute toxicity*, and chronic effects are observable only at high doses. The lethal dose for humans is estimated to be ca. 10 – 12 mL/kg [177]. The toxic effects of DMSO, such as skin rash and itching after dermal application, hemolysis after intravenous infusion, and gastrointestinal disorders after swallowing, depend strongly on the concentration. DMSO – water mixtures have an irritant effect only at concentrations > 70 % DMSO.

In the mammalian organism, sulfoxides can be reduced to sulfides by tissue or microbial enzyme systems. Enzymatic oxidation to sulfones has also been described, therefore the toxic effect of sulfoxides can arise from both of these redox states.

Teratogenic and *mutagenic activity* has been described for DMSO. DMSO strengthens the action of other toxic substances due to absorption through the skin.

In handling DMSO, attention should be paid to the fact that hazardous chemical reactions can occur in some cases. Explosions have been reported as a result of thermal decomposition and on reaction with organic acid chlorides, nonmetal halides, perchloric acid, perchlorates, nitrates, and sodium hydride.

Only limited data can be found in the literature on the toxicity of other sulfoxides.

Sulfonic Acids, Aliphatic

KURT KOSSWIG, Hüls Aktiengesellschaft, Marl, Federal Republic of Germany

1. Properties and Uses 1
2. Production 3
3. References 4

1. Properties and Uses

Alkanesulfonic Acids. In alkanesulfonic acids RSO_3H, a hydroxysulfonyl group is bonded via the sulfur atom to a carbon atom of an alkyl group. Alkanesulfonic acids are strong acids, and the lower members up to heptane-1-sulfonic acid are completely dissociated in dilute aqueous solution. Estimated pK values in aqueous solution of some other strong acids are compared with those of methane-, ethane-, and propanesulfonic acids below [5]:

$C_3H_7SO_3H$	− 1.5
$C_2H_5SO_3H$	− 1.7
CH_3SO_3	− 1.9
p-$CH_3C_4H_4SO_3H$	− 2.7
$C_6H_5SO_3H$	− 2.8
$HOSO_3H$	− 3.0
CH_3OSO_3H	− 3.5
p-$O_2NC_4H_4SO_3H$	− 3.8
CF_3SO_3H	− 5.5
FSO_3H	− 5.6

Methanedisulfonic acid (methionic acid) [*503-40-2*], mp 96 – 100 °C, has the same strength as sulfuric acid.

From heptane-1-sulfonic acid onwards the sulfonic acids increasingly associate in aqueous solution, forming micelles [6]. Pure alkanesulfonic acids attack stainless steel, but the presence of 0.5 to 1 % sulfuric acid hinders corrosion.

The physical properties of some *n*-alkanesulfonic acids are listed in Table 1. Alkanesulfonic acids decompose on distillation at normal pressure, but can be distilled without decomposition under vacuum.

Alkanesulfonic acids darken when stored in the absence of light. They form hydrates, are hygroscopic, and dissolve readily in water. The stable alkali metal, ammonium, alkaline-earth metal, and lead salts also have high water solubility and can be recrystallized from alcohol.

Alkanesulfonic acids with nonterminal sulfonic acid groups are less stable than the alkane-1-sulfonic acids, in particular 2-methylpropane-2-sulfonic acid [*16794-13-1*], *mp* 113 °C [7].

Lower molecular mass alkanesulfonic acids, especially methanesulfonic acid, being strong, nonoxidizing acids, are used as catalysts for esterification, polymerization, and alkylation, and for the production of peroxycarboxylic acids from hydrogen peroxide and carboxylic acids [8]. Their esters are used as alkylating agents. Short- chain alkanesulfonic acids such as butanesulfonic acid, have been proposed as components of industrial cleaning agents, as they can remove both organic and mineral contamination [9].

Perfluorinated Alkanesulfonic Acids [10], [11]. Perfluoroalkanesulfonic acids, which can be obtained by electrochemical fluorination of alkanesulfonic acids, followed by hydrolysis of the resulting sulfonyl fluorides, are the strongest organic acids and are even stronger than sulfuric acid. Perfluoroalkanesulfonic acids are thermally very stable and can be distilled at normal pressure (Table 2). They form crystalline hydrates.

Table 2. Boiling points of some perfluoroalkanesulfonic acids at normal pressure

	CAS no.	*bp*, °C
Perfluoromethanesulfonic acid	[*1493-13-6*]	162
Perfluoroethanesulfonic acid	[*354-88-1*]	178
Perfluoropropane-1-sulfonic acid	[*423-41-6*]	196
Perfluorobutane-1-sulfonic acid	[*375-73-5*]	210 – 212
Perfluoropentane-1-sulfonic acid	[*2706-91-4*]	224 – 226
Perfluorohexane-1-sulfonic acid	[*355-46-4*]	238 – 239

Perfluoroalkanesulfonate anions are good leaving groups [12]. Esters of perfluoroalkanesulfonic acids are therefore used as strong alkylating agents in preparative chem-

Table 1. Physical data of some alkane-1-sulfonic acids

Acid	CAS no.	*bp*/ hPa, °C	*mp*, °C	d_4^{25}
Methanesulfonic acid	[*75-75-2*]	122/1.3	20	1.4844
Ethanesulfonic acid	[*594-45-6*]	123/1.3	− 17	1.3341
Propane-1-sulfonic acid	[*5284-66-2*]	136/1.3	7.5	1.2516
Butane-1-sulfonic acid	[*2386-47-2*]	147/0.9	− 15.2	1.1906
Pentane-1-sulfonic acid	[*35452-30-3*]	163/1.3	15.9	1.1226
Hexane-1-sulfonic acid	[*13595-73-8*]	174/1.3	16.1	1.1047

istry. Trifluoromethanesulfonates are known as triflates and nonafluorobutanesulfonates as nonaflates.

Hydroxyalkanesulfonic Acids. Some hydroxyalkanesulfonic acids and their derivatives are important in industry.

The sodium salts of 1-hydroxyalkane-1-sulfonic acids are readily crystallizable compounds which are formed from aldehydes and sodium bisulfite in neutral solution. In an acidic or alkaline medium they decompose into their components. They are used for the sulfonalkylation of compounds with an active hydrogen atom, in particular sodium hydroxymethanesulfonate (from formalin and sodium bisulfite), for example:

$$RNH_2 + CH_2O + NaHSO_3 \longrightarrow RNH{-}CH_2SO_3Na + H_2O$$

Isethionic acid, 2-hydroxyethanesulfonic acid [*107-36-8*], is used as an intermediate in numerous syntheses. It is generally used in the form of its readily accessible stable sodium salt [*1562-00-1*], *mp* 192 – 194 °C, for example:

$$RCOCl + HOCH_2CH_2SO_3Na \longrightarrow RCOOCH_2CH_2SO_3Na + HCl$$

Isethionic acid is the starting material for the industrial synthesis of taurine (2-aminoethanesulfonic acid [*107-35-7*]), *mp* 317 °C dec., and *N*-methyltaurine (2-*N*-methylaminoethanesulfonic acid [*107-68-6*]), *mp* 245 °C. Taurine is a naturally occurring substance, formed in organisms by oxidation of cysteine, and is a building block of taurocholic acid. The derivatives of isethionic acid, taurine, and *N*-methyltaurine, especially their fatty acid derivatives, are important wetting, washing, and dispersion agents in body and household cleaning agents, and also in textile processing.

1,3-Propanesultone [*1120-71-4*] [13], *mp* 31 °C, *bp* 150 °C (13 hPa), d_4^{40} 1.392, the internal anhydride of 3-hydroxypropane-1-sulfonic acid [*15909-83-3*] is a strong alkylating agent, for example:

Reaction products of propanesultone with alcohols, phenols, thiols, sulfides, and amides have been proposed as tensides, leather auxiliaries, antistatic agents, and bacteriostatic agents. Cellulose becomes soluble when treated with propanesultone. Polyamide fibers treated with propanesultone can be dyed more easily. However, since propanesultone has been shown to be a strong carcinogen, it is no longer important as a synthon.

Vinylsulfonic acid, ethenesulfonic acid [*1184-84-5*] [14], *bp* 95 °C (1 Pa), is derived from isethionic acid and can only be kept below 0 °C, as it polymerizes rapidly. It is preferable to use its sodium salt in aqueous solution or its esters [e.g., methyl ester, *bp* 54 – 60 °C (30 – 50 Pa), n_D^{20} 1.4310]. The sodium salt [*3039-83-6*] or the esters of vinylsulfonic acid add to compounds with activated hydrogens (sulfonethylation) for example:

$$NaHSO_3 + CH_2{=}CHSO_2OR \longrightarrow NaO_3SCH_2CH_2SO_2OR$$

The addition products with alcohols, phenols, thiols, and amines have been proposed as plasticizers for poly(vinyl chloride), as cross-linking agents, emulsifiers, microbicides, fungicides,

and fungistatic agents. Vinylsulfonic acid and its salts are also suitable monomers for polymerization reactions [15], [16]. Esters of vinylsulfonic acid are powerful alkylating agents: phenol is converted smoothly into anisole with methyl vinylsulfonate in alkaline solution, even at room temperature.

Allylsulfonic acid, 2-propene-1-sulfonic acid [*1606-80-8*], *bp* 180 °C (0.1 Pa), is unstable and is preferably used in the form of its sodium salt [*2495-39-8*] in aqueous solution as a comonomer for polymerizations [15].

Methallylsulfonic acid, 2-methyl-1-propene-3-sulfonic acid [*3934-16-5*], is also predominantly used in the form of its aqueous sodium salt [*1561-92-8*] as a comonomer in polymerizations. It improves, for example, the dyeability of fibers, especially polyacrylonitrile fibers.

2. Production

Alkanesulfonic Acids. Alkanes do not react specifically with sulfur trioxide or oleum, alkanesulfonic acids being among a number of products. Methanesulfonic acid and sulfur trioxide give methionic acid as the only product in good yields. Starting from alkanes, alkanesulfonic acids are smoothly obtained by sulfoxidation or sulfochlorination [17] (see → Surfactants, Chap. 6.2.3.). However, mixtures of positional isomers are formed in these reactions.

Uniform, defined alkanesulfonic acids are obtained by Strecker synthesis from alkyl halides, preferably alkyl bromides, and alkali metal or ammonium sulfite, or by reaction of the corresponding Grignard reagent with sulfur dioxide and subsequent oxidation. The oxidation of thiols with nitric acid, potassium permanganate, or hydrogen peroxide/glacial acetic acid is frequently used, as is the oxidation of thiocyanates and disulfides, all of which are obtained from alkyl halides.

Starting from 1-alkenes the sodium salts of alkane-1-sulfonic acids are obtained by the addition of sodium bisulfite in a radical-initiated reaction [9], [18].

2-Hydroxyalkane-1-sulfonic acids, especially isethionic acid, are produced by the reaction of 1,2-epoxides (e.g., ethylene oxide) with aqueous sodium bisulfite. The reaction of ethylene with sulfur trioxide gives carbyl sulfate (*mp* 107 – 108 °C), which reacts with water to give ethionic acid [*461-42-7*] (sulfuric acid half ester of 2-hydroxyethane-1-sulfonic acid), and on heating to give isethionic acid [*107-36-8*] [19]:

Ethionic acid is also obtained by the reaction of sulfur trioxide with ethanol.

The methyl-substituted carbyl sulfate, obtained analogously from propene and sulfur trioxide, gives 1-propene-1-sulfonic acid [*97141-05-4*] on decomposition.

1,3-Propanesultone is obtained by elimination of water from 3-hydroxypropane-1-sulfonic acid [20], whose sodium salt is formed by radical-initiated addition of sodium bisulfite to allyl alcohol [21]:

$$HOCH_2CH=CH_2 + NaHSO_3 \longrightarrow HOCH_2CH_2CH_2SO_3Na$$

3-Hydroxypropane-1-sulfonic acid is obtained on acidification.

Vinylsulfonic Acid. The alkaline hydrolysis of carbyl sulfate or ethionic acid gives the vinylsulfonate salt directly:

Sodium vinylsulfonate can also be produced by dehydrochlorination of sodium 2-chloroethane-1-sulfonate with aqueous sodium

hydroxide. The chloroethanesulfonate is produced by sulfochlorination of ethyl chloride and subsequent hydrolysis of the 2-chloroethane-1-sulfonyl chloride, or by treatment of sodium bisulfite with vinyl chloride [14].

Allylsulfonic Acid. Only the sodium salt of allylsulfonic acid is used in industry. It is obtained by treatment of allyl chloride with aqueous sodium bisulfite [22].

Methallylsulfonic Acid. Dimethylcarbyl sulfate cannot be obtained from isobutene and sulfur trioxide, as the methallylsulfonic acid reacts further to give methallyldisulfonic acid:

The formation of the latter can be suppressed by complexation of the sulfur trioxide, for example, with *N*,*N*-dialkylcarboxylic acid amides [23]. However, in industry methallylsulfonate is preferably produced from methallyl chloride and sodium sulfite [24].

1. Introduction

Sulfur is the fifteenth most common terrestrial element, and the ninth most abundant element in the universe. It is widely distributed in nature in different compounds as well as in pure form. The mean sulfur content of the lithosphere is estimated to be ca. 0.05 %. In massive elemental form, sulfur is often referred to as brimstone.

Sulfur is of great industrial importance, though relatively little (ca. 10 %) is used in the elemental form, in the production of carbon disulfide, rubber, pesticides, pharmaceuticals, and cosmetics. By far the greatest part is used in the form of sulfuric acid and sulfur dioxide.

Elemental sulfur is recovered from volcanic and other surface deposits by a number of processes.

The sources of sulfur for the production of sulfuric acid and sulfur dioxide are often sulfur compounds produced as secondary products, e.g., as sulfur dioxide from the processing of sulfide ores of nonferrous metals.

Elemental sulfur is often obtained via hydrogen sulfide during the purification of sulfur- containing natural gas or raffination

of crude oil; after conversion of H_2S to sulfur, the latter is stored or transported to sulfuric acid plants or to purification; it is easier, safer, and cheaper to store and transport sulfur than sulfuric acid or sulfur dioxide.

Because of the increasing production of sulfur-containing byproducts, the relative contribution of mined brimstone production is decreasing: from 47 % in 1979 to 37 % in 1989.

Huge amounts of sulfur compounds contained in coal are converted in thermal power stations to sulfur dioxide which must be recovered for environmental reasons; as the product is highly dilute, it is very difficult to recover the sulfur economically in usable forms, such as the element, sulfuric acid, or concentrated sulfur dioxide; it is easier to remove it as calcium or sodium sulfate or sulfite, even though the major part cannot be marketed and has to be disposed of as a waste product.

Figure 1 shows the principal sulfur sources and processing routes. Table 1 summarizes sulfur production in the major regions of the world.

Table 1. Production of sulfur in 1992 (10^3 t sulfur)

Region	All forms	Brimstone
Europe including Turkey, without former Soviet Union	11 461	6 845
Former Soviet Union	8 331	5 181

2. Historical Background

Sulfur has been known since ancient times. The Greeks called it *theion*, the Romans *sulphurium.* Genesis refers to it as brimstone — the stone that burns. Its characteristic yellow color, its combustibility, and the pungent odor of its combustion products attracted attention, and led to its use in religious ceremonies. As early as ca. 2000 B.C. the Egyptians are known to have used the gases from sulfur combustion to bleach fabrics. Certain Egyptian dyes, known to have existed in the sixteenth century B.C., could not have been prepared without the use of sulfur compounds. HOMER mentions sulfur as a disinfectant; the Romans used it as a dermatological remedy. PLINY regarded sulfur as one of the most singular kinds of earth, and an agent of great power over other substances. Sulfur was probably one of the components of so- called Greek fire.

Alchemists thought that sulfur was a fatty mineral substance that could be melted to a combustible oil. It was supposed that all combustible materials contained sulfur. In 1777, LAVOISIER classified it as an element, but DAVY, in 1808, still thought that sulfur was a compound containing oxygen, similar to resins.

In Europe, sulfur gained great importance after the Chinese invention of gunpowder was introduced in the early 1200s. The first commercial sulfur was produced in Sicily early in the 1400s. With the advent of industrialization toward the end of the 1700s, sulfur became more and more important in the form of sulfuric acid and fertilizers.

3. Properties

Sulfur is a nonmetallic element of group 16, with valence –2 to +6, atomic number 16, atomic mass 32.064. It is tasteless and odorless.

3.1. Physical State

Elemental sulfur occurs in several different allotropic forms, which differ in solubility, relative density, crystalline form, etc., [1-3].

The crystalline rhombic α-form is the most common type of solid sulfur. At room temperature, it is pale yellow; at low temperature it becomes lighter in color, almost white at the temperature of liquid air. It is stable up to 95.5 °C, at which it is transformed to β-sulfur.

The crystalline monoclinic β-form occurs as needle-like crystals, and is stable up to the melting point, 119.3 °C. It is almost colorless and is slowly converted to the α-form on cooling below 95.5 °C.

The γ-form is also crystalline monoclinic, but with a different lattice from that of the β-form. It is light yellow, nacreous, and metastable.

The amorphous μ-form exists in the liquid phase at ca. 160 °C, and is responsible for the increased viscosity at this temperature. It can be preserved as a plastic solid by instantaneous cooling of the melt, but after 1 – 2 d, it becomes hard. This form, insoluble in carbon disulfide, is an amorphous polymer, molecular mass ca. 60 000 – 150 000.

The π-form is a light yellow melt, produced at 119.3 °C from the solid α-form. This is the “ideal” melting point. After several hours, the melting point decreases to 114.5 °C, the “natural” melting point. This effect is explained by transformation of a fraction of the S_8 molecules to the liquid.

The π-form probably consists of chains of S_6, S_7, and S_x and is less soluble in carbon disulfide than the α-form.

Other crystalline modifications are also known, but are unstable at all temperatures and have not yet been studied thoroughly.

The proportions of different types of sulfur molecules in the liquid are given in Figure 2 [3].

Figure 2. Composition of liquid sulfur as a function of temperature

Sulfur vapor dissociates at higher temperature, from S_8 through the intermediate species S_6 and S_4, to S_2 (Fig. 3). At temperatures above ca. 2000 °C, the gas consists only of sulfur atoms.

Figure 3. Composition of sulfur vapor as a function of temperature

Figure 4 shows a phase diagram for sulfur [4]. Because of the wide range of pressures, a logarithmic scale is used, which obscures the transition points from the stable to the metastable equilibrium of rhombic, monoclinic, and molten sulfur with the vapor phase.

Figure 4. Sulfur phase diagram [4]

More information on the physical state of sulfur can be found in the literature [5-10].

3.2. Viscosity

The viscosity of a pure sulfur melt is shown in Section Other Physical Properties . If the melt temperature is raised, the viscosity first decreases (as is usual for liquids) from 0.017 Pa · s at ca. 120 °C to a minimum value at ca. 158 °C. Above this temperature, the viscosity rises steeply to a maximum value at 186 – 188 °C, at which the melt is dark red. Above this temperature, the viscosity decreases again. This striking phenomenon is interpreted as follows: As the temperature is increased, the S_8 rings are progressively broken up into biradicals whose concentration, at ca. 160 °C, reaches the value necessary for spontaneous polymerization to μ chains. When the temperature rises further, the long chains are increasingly cracked, so that the viscosity decreases [11].

The formation of μ-sulfur is strongly enhanced by even small amounts of impurities. Paradoxically, however, the viscosity of an impure sulfur melt increases during melting to a much smaller extent than that of a pure one; the impurities favor the formation of shorter chains of the μ-sulfur.

The viscosity of liquid sulfur is greatly reduced by the presence of hydrogen sulfide at saturation pressures of 120 – 460 kPa. The viscosity of sulfur in equilibrium with hydrogen sulfide at ca. 100 kPa has been calculated [10]. Calculated values for H_2S partial pressures in the range 0.1 –100 kPa are shown in Figure 5 [12].

Figure 5. Viscosity of liquid sulfur [12]

3.3. Other Physical Properties [1], [13-18]

The melting/solidification point of normal sulfur is 119.3 °C – 114.5 °C, depending on the mode of heating. The melting points of the various allotropes together with other physical data are listed below [1]:

Density of solid at 20 °C, kg/m^3

A plot of thermal conductivity versus temperature is shown in Figure 6 [1].

Figure 6. Thermal conductivity of solid and liquid sulfur

Sulfur has four naturally occurring stable isotopes: ^{32}S (95 %), ^{33}S (0.75 %), ^{34}S (4.21 %), and ^{36}S (0.02 %). Radioactive ^{35}S, used in tracer studies, has a half-life of 88 d. The other isotopes: ^{29}S, ^{30}S, ^{31}S, ^{38}S, and ^{39}S are all very short-lived [13].

Sulfur is insoluble in water, but soluble in a number of solvents, such as carbon disulfide, hydrated naphthalenes, and chlorinated aromatics. Disulfur dichloride (sulfur monochloride) dissolves large amounts of sulfur.

Sulfur has extremely low thermal and electrical conductivity, and acquires a strong, negative electric charge by friction. These properties are of considerable importance in its large-scale commercial transport and handling.

3.4. Chemical Properties [1], [13]

Sulfur is one of the most reactive elements; it reacts directly with most elements except iodine, gold, platinum, and the noble gases. In humid air it is weakly oxidized, forming traces of sulfur dioxide and sulfurous acid. At ca. 250 °C, sulfur ignites in air and burns with a blue flame, but the presence of sulfur dioxide significantly raises the ignition point. Finely divided sulfur reacts with metal powders, usually exothermically, to metal sulfides, e.g., iron sulfide, zinc sulfide, or cuprous sulfide. Sulfur reacts with nitrogen to form various sulfur – nitrogen compounds. In the absence of oxidizing agents it is stable to hydrochloric acid, but this stability is diminished by the presence of iron. Concentrated sulfuric acid scarcely reacts with sulfur at low temperature; at 200 °C sulfur dioxide is formed. Nitric acid, and even more so aqua regia or hydrochloric acid with oxidizing agents such as potassium chlorate or bromine, attack sulfur to form sulfuric acid. Concentrated nitric acid in the presence of bromine oxidizes sulfur in a strongly exothermic reaction. When sulfur is heated with aqueous ammonia, ammonium polysulfide and thiosulfate are formed. Boiling with aqueous solutions of alkali and alkaline-earth metals also produces polysulfides and varying amounts of thiosulfates. There is a great variety or organic sulfur compounds; some of them are essential to living organisms.

4. Raw Materials for Sulfur Production

World resources of sulfur have been estimated at 25×10^9 t: 4.0 % as elemental sulfur; 4.1 % in sulfide ores; 83.6 % in coal; 3.0 % in crude oil; 5.3 % in natural gas.

4.1. Elemental Sulfur Resources

Ores containing native sulfur are found exclusively in the upper layers of the Earth's crust and are either of sedimentary or volcanic origin. Ore bodies worthy of large-scale exploitation are restricted to a few regions, but there are also many smaller deposits of local importance.

Significant *sedimentary deposits* are located in the following areas:

1. Gulf of Mexico basin — in the states of Louisiana and Texas, and in Mexico
2. Mediterranean basin — main deposits in Sicily, but others on the Italian mainland, and on the French and Spanish coasts
3. Eastern European basin — along the Volga river and the coast of the Caspian Sea along the Caucasus mountains
4. Central European basin — north of the Carpathians in Poland
5. Central Asian basin — in Turkmenistan, Uzbekistan, Russia and Afghanistan

Deposits of *volcanic origin* are found in:

1. East Asian basin — along the Philippines, Japan, the Kuril Islands, and the Kamchatka Peninsula
2. Cordillera basin — along the western side of North and South America, through Mexico, Peru, Bolivia, and Chile

4.2. Sulfide Ores

The main deposits of pyrite are in Spain (Huelva) and Portugal (Alemtejo). Pyrite is also mined in Norway (Lökken), in Cyprus, in Germany (Westphalia), in northern Italy, and in Russia.

By far the largest proportion of copper, zinc, lead, nickel, and cobalt is obtained from sulfide ores. The most important deposits of copper ores are on the west coasts of North and South America, in Zaire, and in Zimbabwe. The main source of lead ores is the Tri-State region of the United States.

4.3. Fossil Fuels

Coal. All coals contain sulfur; the amount depends on their type and origin. In the United States, the coals from the eastern, midwestern, and southern states are predominantly high in sulfur, containing 2 – 4 %, while those from the western states mostly contain less than 1 % [19]. The sulfur content of German lignite is usually 1 – 2 %, rarely > 5 %; that of coal from the Ruhr has 0.5 – 2.5 % [20]. South African coals range from ca. 0.3 % to ca. 2.8 % [21].

Occasionally, larger amounts of pyrite (marcasite) occur in coal, which may necessitate mechanical or chemical separation. However, the major part of the sulfur is organically bound in the coal. When the coal is coked or gasified, most of the sulfur escapes as hydrogen sulfide, which has to be removed from the gases and converted into elemental sulfur. When the coal is combusted, the sulfur is converted to sulfur dioxide, and escapes to the atmosphere, if not removed from the flue gas. The quantity of sulfur discharged in this way exceeds the total amount of sulfur consumed for industrial purposes by a large margin.

Crude oil mostly contains 0.1 – 2.8 wt % sulfur. A few individual crudes contain over 3 % [22]. The sulfur is removed for the most part during crude oil processing, giving substantial quantities of hydrogen sulfide and thiols. World production of crude oil increased steadily from 2654×10^6 t in 1985 to 3019×10^6 t in 1992 [23].

Natural gas contains sulfur, mainly as hydrogen sulfide; the proportion of sulfur varies widely. Some accumulations contain no sulfur at all; in other cases the hydrogen sulfide content is extremely high. The gas from Lacq (southwestern France), for instance, contains 15 % H_2S, while some of the gases from Canada (Alberta and northeast British Columbia) contain ca. 30 % H_2S. World production of natural gas has continued to grow (equivalent to $73\,083\times10^{12}$ J in 1990 [24]).

4.4. Sulfates

Among the naturally occurring sulfates, only calcium sulfate has ever been of any real importance as a source of sulfur, and then only in the production of sulfur dioxide for sulfuric acid manufacture. The economics of this process are now so unfavorable that it is only used under very special circumstances.

Elemental sulfur has never been extracted from sulfates on any significant scale, principally because of the unfavorable energetics of the process, although experimental work has been done on both chemical [25], [26] and microbiological [27-29] methods of reducing gypsum to hydrogen sulfide.

[Top of Page]

5. Production from Native Deposits

Depending on the geology of the deposit, sulfur ores are excavated by normal open-pit or underground mining methods.

Under the special geological conditions in the deposits around the Gulf of Mexico, and in one or two other places, elemental sulfur is produced directly by fusion with hot water (Frasch process).

Various combinations of flotation, autoclaving, filtration, melting out, etc., have been proposed for extracting sulfur from mined ores [30]. In practice, only a few processes are important, and their application depends on the nature of the deposit and the economic conditions (e.g., mining rights, energy and labor costs).

The extraction methods, of which some are only of historical interest, can be classified as follows.

5.1. Flotation

Flotation can be applied easily to the concentration of sulfur ores [31], [32]. After grinding to a sufficiently fine size (> 50 % smaller than 5 µm) the sulfur is readily flotated with foaming agents such as pine oil, cresylic acid, and amyl alcohol. Flotation is enhanced by collectors in a neutral or basic slurry. When the gangue contains limestone, it is recommended that water glass or soda be added.

Flotation gives sulfur concentrates of 70 –90 %. The method has the drawbacks that the concentrate has to be dried, and that it does not produce pure sulfur directly, as do most other processes.

5.2. Melting Out

In Sicily (which until 1904 had a virtual monopoly in sulfur production [33]) melting-out processes were predominant. Sulfur melts at 112 – 114 °C, but becomes highly viscous at temperatures above 158 °C (see Section Other Physical Properties), so the permissible temperature range for melting out is small. Furthermore, sulfur is a poor heat conductor and the gangue absorbs sulfur and retains it in its capillary structure. Therefore, in most cases, the yield is not very high.

Originally, sulfur was melted out in mound-like ore piles known as *calcarelle*, built up on a small hearth equipped with a drain hole, and simply ignited. Only one-third of the sulfur was recovered; two-thirds were lost to the atmosphere as sulfur dioxide.

Calcarone. A substantial improvement to the calcarelle was achieved by covering the ore pile with soil, as practiced in charcoal-making. In the late 1800s, this was the main method in Sicily. To build a calcarone, a circular brick wall with an inclined base was erected on a mountain slope. At the lowest point, there was a duct through the wall to allow air to enter and the sulfur to run out. Coarse and fine lump ore were piled up to make a heap with diameter ≤ 30 m and height ≤ 6 m. The piles were covered with fine ore and residues from earlier operations, sealed with gypsum and clay, and ignited on the uphill side at a point somewhat below the peak. The burning rate was controlled by openings in the outer layer, and the burning front advanced slowly toward the outlet. The sulfur yield was 30 – 60 %.

Chamber Furnaces. The melting process was substantially accelerated by the introduction of the chamber furnace, developed by GILL in 1890, and consisting of two chambers. In the first of these, the sulfur residue from melted-out ore was burned, and the resulting hot gases were passed through a duct into the second chamber, where they melted out the sulfur from fresh ore. So as not to lose any time in charging and emptying, furnaces were built with five or six chambers. These were generally introduced from 1927 onward, and gave yields ≤ 78 %.

As they required neither external fuel nor power, and the capital costs were low, they were excellently suited to Sicilian conditions. It was, however, impossible to connect more furnaces in line, as in the case of the annular chamber kilns used in brickyards, because the higher temperature required to maintain the draught made the sulfur too viscous.

Melting Out with Steam. As early as 1927, steam-heated autoclaves were being used in Sicily. Cylindrical autoclaves, slightly inclined from the horizontal, with diameter ca. 1 m and length 4.75 m, were in general use. They were equipped with a removable cover at the top. Lump ore was introduced on small wagons built to fit inside the autoclave. Steam of 400 – 500 kPa was used for melting out. For ore with 25 – 35 % S, the sulfur yield was about 47 – 55 %. For this reason, only high-grade ores were used in the steam melting process, and the residues, with 13 – 14 % S, were generally passed on for further melting out in a chamber furnace.

Melting Out with Superheated Liquids. Superheated water at 150 °C, as used in the Frasch process, is too expensive on account of the need for pressure autoclaves. Without applying pressure, it is still possible to extract the sulfur, either by melting with salt solutions of high boiling point, or by leaching with inorganic or organic solvents. Examples of recommended media are concentrated solutions of calcium, magnesium, and zinc chlorides, sodium sulfide solution, and solvents such as chlorinated [34], [35] and unchlorinated hydrocarbons [36], and carbon disulfide [37-39].

5.3. Distillation

It is not practicable to melt out the sulfur content of a sulfur ore in an externally heated vessel. Sulfur is such a poor conductor of heat that, with the temperature limitations imposed by viscosity, an extremely large heating surface is required. It is theoretically more favorable to distill the sulfur out of the ore. The ore is either heated in a retort, or brought into direct contact with solid heat sources. For high-grade ores, the retort process has acquired local importance. In Chile, raw and sublimed sulfur are recovered from high-grade ores in iron retorts [40]. In Japan, ores with > 25 % sulfur mixed with pyrite are processed by a similar method. In the Yakutori process, the ore is heated by external firing with coal in small retorts (0.4 m^3) made of 13 % chromium steel, which hold 0.24 t of ore. Up to 100 retorts are coupled to form a furnace. For 1 t of recovered sulfur, 0.41 t of coal is consumed [41].

On account of the poor thermal conductivity of sulfur ores, it has been proposed to heat them with hot inert gases. In spite of many proposals and practical tests, it has proved impossible to exclude oxygen and moisture completely, and inevitably sulfur dioxide and sulfuric acid form. Under the process conditions, these are strongly corrosive, and only processes that use brick-lined equipment (e.g., rotary kilns) and recycle the sulfur dioxide- containing waste gases are suitable. In any

case, this method is not competitive at current sulfur price levels.

5.4. Flotation with Melting Out

In 1953, important sulfur deposits were discovered near Tarnobrzeg and Machov in the Piaseczno region of Poland. They are located near the surface, and can be extracted by open-pit mining, after removal of ca. 50 m overburden. The ore, 20 – 25 % sulfur, is concentrated by flotation. The concentrate, 25 % sulfur and 75 % water, is dewatered by filtration and a drum filter to a water content of 50 %. The sulfur is melted out of this concentrate with steam (ca. 5 MPa) in 50-m^3 autoclaves.

The pit water contains hydrogen sulfide (40 – 400 mg/L). This is removed by stripping with air in a packed spray tower. The stripping air is then scrubbed in a second tower with an alkaline iron (II) hydroxide suspension. The colloidal sulfur obtained is used in agriculture [42]. A similar technique of flotation and autoclaving has been used for refining volcanic sulfur in Chile [43].

5.5. The Frasch Process

By today's standards, the only economic method of extracting sulfur from native deposits is in situ melting by the Frasch process. It is the only way of obtaining marketable sulfur from a native deposit that does not necessitate two discrete operations (mining followed by processing). It was originally developed to take advantage of a very special set of geological circumstances that are virtually confined to the area around the Gulf of Mexico. Although the technique has been further developed for use on less ideally structured deposits in Poland and Iraq [44], [45], technical and economic considerations generally limit its use to the south-east (Gulf) region of the United States and the Mexican sulfur fields.

5.5.1. *Structure of "Fraschable" Sulfur Deposits*

The geological structure around the Gulf of Mexico is a deep sedimentary basin with cretaceous strata underlying tertiary deposits of sand and clay. In a number of places intrusions of rock salt from lower levels have distorted the cretaceous layers into dome-like structures. The Gulf of Mexico has about 400 such domes (Fig. 7 A). They have a diameter of a few hundred meters up to several kilometers. Immediately overlying the salt are layers of anhydrite (calcium sulfate), dolomite (calcium-magnesium carbonate), and limestone (calcium carbonate), which together form the so- called cap rock. The anhydrite and tertiary clays which lie over the limestone are effectively impervious. The theory is that, in the more porous layers of dolomite and calcium carbonate, oil once accumulated. Bacteria in the oil are then thought to have reduced sulfate from the anhydrite to elemental sulfur [46], and may also have been responsible for the virtual disappearance of the oil in these accumulations. The elemental sulfur is, therefore, dispersed through the dolomitic and limestone layers of the cap rock. The thickness of the sulfur- containing strata is 1 – 75 m and the sulfur content varies from a few percent to ca. 50 %, so only about 20 domes contain sulfur in economically significant amounts.

5.5.2. *Outline of the Process*

The process, developed by HERMAN FRASCH between 1894 and 1903, consists of injecting large quantities of hot water directly into the deposit, and then pumping the molten sulfur to the surface. By a method akin to that used by the oil industry, a well is drilled through the cap layers and the sulfur-bearing layers down to the top of the anhydrite stratum, at a depth of ca. 50 – 800 m. Three coaxial pipes are introduced into the borehole (Fig. 7 B). The outermost pipe, with a typical diameter of ca. 200 mm, reaches to the bottom of the borehole; its lower end is perforated with slots. The middle (sulfur delivery) pipe is somewhat shorter, ending about halfway down the perforated part of the outer pipe. A collar on the end of the middle pipe closes off the annular space between the two pipes from the space below the end of the middle pipe. Water at ca. 165 °C, under sufficient pressure to keep it from boiling (2.5 – 3 MPa), is forced down the annular space between the outer and middle tubes, through the perforations in the outer tube above the collar, and into the deposit. The water penetrates into the cracks, pores, and larger voids of the sulfur-bearing limestone, and heats and melts the sulfur around the end of the pipe. The molten sulfur, of higher density than the water, collects at the bottom of the borehole. After a reservoir of molten sulfur has been established there, which requires heating for 24 h or longer, the hot water is turned off and the sulfur can flow through the bottom openings of the outer pipe into the middle pipe. As sulfur has about 1.8 times the density of water, it will only rise about halfway up the middle tube under the influence of hydrostatic pressure. Hot compressed air at about 3 MPa is injected through the innermost pipe, which extends about two-thirds of the way down the borehole, and therefore ends well below the surface of the sulfur column in the middle tube. The resulting foam of sulfur and air is very light and easily rises the rest of the way to the surface. Injection of hot water is continued to maintain the melting process. The transport air rate must correspond to the sulfur melting rate.

At the surface, the sulfur froth is deaerated and transferred to a heated storage tank, or to a sulfur-forming device, to be solidified as slates, prills, pellets, or pastilles. Because the rate at which water is pumped into the sulfur-bearing stratum is much higher than the rate of sulfur production, the pressure tends to increase, so the water must be drained from the deposit through ancillary boreholes, usually located on the flanks of the dome.

5.5.3. *Sulfur Purity*

The effective range of a borehole is 50 –800 m; its output can be as much as 300 t/d. The extracted sulfur can be quite

pure (99.7 – 99.8 %) and light yellow in color. If the sulfur is contaminated by even quite small amounts of bituminous residues from the oil associated with the genesis of the sulfur deposit, it is brown or occasionally blackish in appearance. This so- called dark sulfur may contain ca. 0.08 – 1 % of bituminous material (measured as carbon). The majority of this material is present as complex organic sulfides (carsul), which are responsible for the dark color. Because carsul is dissolved in the sulfur, it cannot be removed by simple filtration. It can, however, be removed to some extent by filtration through diatomaceous earth, which absorbs it [47]. Alternatively, the sulfur can be treated with concentrated sulfuric acid, to char and sulfonate the carsul, after which it is either mixed with diatomaceous earth to absorb the reaction products, or extracted with superheated water [48]. In general, no treatment is completely effective in removing organic impurities from dark sulfur. The most effective one, distillation [49], is hardly considered economic today as a routine means of purifying large tonnages of sulfur. In fact, dark sulfur is acceptable for many uses, except when the organic content is rather high. If dark sulfur is used for making sulfuric acid, the moisture resulting from the combustion of the organic materials may give rise to acid mists, which can cause problems with corrosion and pollution.

5.5.4. *Energy Consumption*

The greatest problem facing the Frasch mines is the cost of energy. The most important factor is the “water ratio”; depending on the geological conditions at the bottom of the borehole, 3 – 38 m^3 of water at 165 °C is required to produce 1 t of sulfur.

The U.S. industry has always used natural gas as fuel. The enormous increase in gas prices over the past few decades has forced the industry to investigate the possibilities of cheaper fuels, e.g., heavy fuel oil, and to consider measures to improve mining efficiency and economics. These include improvements in borehole techniques, as well as the relatively old concept of combining the Frasch operation with the generation of electricity, which can be sold locally [50]. Another possibility to save energy is the reuse of the hot injection water. The problem is contamination of this water by hydrogen sulfide, other noxious and corrosive sulfur compounds, and mineral constituents.

5.5.5. *The U.S. Frasch Industry*

Sulfur production on the Gulf coast of Louisiana and Texas began with Union Sulfur's mine in 1895 and, by 1963, there were 26 plants using the Frasch process. The annual production of individual plants ranged from a few hundred to several million tonnes. The Union Sulfur mine produced about 9.5×10^6 t of sulfur between 1895 and 1924. At first, all plants were built on the mainland, but some of the more recent mines have been located offshore in the Gulf of Mexico, on artificial islands in the open sea, complete with the necessary drilling rigs and boiler plants. The liquid sulfur is pumped through insulated piping, laid on the ocean bed, into storage tanks on the coast, or is directly loaded in liquid form into tankers for immediate transport to the consumer.

The largest mining project of this type is the Main Pass offshore platform, operated by Freeport Sulfur, and located off the Louisiana coast, some 140 km southeast of New Orleans. The 1.8-km platform (the largest offshore structure in the Gulf of Mexico) is designed to accommodate some 300 workers; sulfur production is specified at 5500 t/d. Main Pass, with its 68×10^6 t of proven recoverable sulfur is the largest existing sulfur reserve in North America, and is planned to be in production for at least 34 years [51].

The great challenge for the U.S. Frasch industry was the emergence of large-scale production of sulfur from the gas fields of France and Canada, which as a byproduct is priced on different criteria from Frasch sulfur. Frasch production in the United States decreased from 61 % of total sulfur production in 1980 to ca. 24 % in 1992; it is operated now by just three companies, all of which have been in the sulfur industry for many years. They have six operating mines, but only two have sufficient reserves to keep them operating through the 1990s.

Company production figures for 1987 were as follows:

- Freeport Sulfur (Garden Island Bay, Grand Isle, and Caminada), ca. 1.22×10^6 t/a.
- Main Pass, which came on stream in 1993, $(2.0 – 2.5)\times10^6$ t/a.
- Pennzoil Sulfur (Culberson mine, exploration in the Delaware Basin), ca. 1.5×10^6 t/a.
- Texasgulf, part of the Elf Aquitaine Group of France (Boiling Dome at Newgulf), ca. 0.26×10^6 t/a.

With the majority of elemental sulfur on the world market now coming from other sources, the U.S. Frasch producers can no longer control the price of sulfur, and many operations have become uneconomic. Total production reached a maximum in 1974, at 8.03×10^6 t in response to a peak in world demand. In 1987, production of Frasch sulfur was 3.2×10^6 t, accounting for 34 % of the total produced in the United States. This represents falls of 21 % and 36 % from the 1986 and 1985 figures. In 1988 and 1989, production was 3.17 and 3.89×10^6 t [52], [53].

5.5.6. *The Mexican Frasch Industry*

The Mexican Frasch industry is concentrated on three salt domes on the Isthmus of Tehuantepec, near the port of Coatzacoalcos on the Gulf of Mexico. The salt domes have been exploited for sulfur by the Frasch method for nearly 40 years, and until recently five Frasch mines were operating in the area. These mines are owned by Compania Azufrera Panamericana SA (APSA) which is 96 % state owned, and by Compania Explorado de Isthmo SA (CEDI), 34 % owned by Texasgulf and 66 % state owned.

Frasch production in Mexico was approximately constant between 1985 and 1989 (1.55×10^6 t in 1985, 1.53×10^6 t in 1989), but dropped to 1.02×10^6 t in 1991 [54-56].

The 1991 production figures were as follows:

Coachapa, Veracruz (APSA), 110 000 t/a.
Jaltipan, Veracruz (APSA), 360 000 t/a.
Otapan, Veracruz (APSA), 50 000 t/a.
Texitepec, Veracruz (APSA on behalf of CEDI), 500 000 t/a.

[Top of Page]

6. The Claus Process

6.1. Occurrence of Hydrogen Sulfide

Hydrogen sulfide per se is relatively little used in chemical processing, and is no longer very common as a byproduct of the chemical industry, but it is a common byproduct of fuel processing.

Most fossil fuels — natural gas, petroleum, and coal — contain some chemically combined sulfur. In natural gas it is present mainly as hydrogen sulfide, with only minor proportions of organic sulfur compounds. Petroleum contains a variety of organic compounds, such as thiols, alkyl and aryl sulfides and disulfides, thiophenes, and more complex condensed aromatic heterocyclic sulfur compounds. These are also present in coal, which usually contains a high proportion of inorganic sulfur as the iron sulfides pyrite and marcasite.

When crude oil is distilled at the refinery, the sulfur is partitioned between the various product fractions in proportion to their relative density; very little is found in the lightest fractions, while the heaviest distillates and the residues contain proportionately more sulfur than the original crude oil. These were formerly used as industrial fuel, but this contributed significantly to atmospheric sulfur dioxide pollution, and most industrial countries have now introduced regulations which specify a limit either on the sulfur content of fuel oil or on the amount of sulfur dioxide that may be discharged into the atmosphere from a given installation. Either way, the use of high-sulfur fuel oil is effectively outlawed, and fuel oil has to be desulfurized at the refinery. Demand for the lighter products has increased at the expense of heavy products, and refiners have responded by introduction processes which convert heavy distillates and residues into lighter products.

In both the desulfurization of fuel oil and the conversion of heavy fractions into light products, organic sulfur compounds are converted mainly into hydrogen sulfide. Much of this leaves the process in admixture with other gaseous materials, such as hydrogen (used as a reactant in some processes and produced as a byproduct in others) and byproduct hydrocarbons. Such gas streams are amalgamated with other hydrocarbon-containing off-gases to form the refinery fuel gas.

Some of the hydrogen sulfide released in the processing of heavy fractions becomes absorbed into aqueous condensates and scrubber effluents, where it associates with dissolved ammonia (from the decomposition of organic nitrogen compounds in the oil) to form ammonium sulfides. These effluents are referred to collectively as “sour water”.

For economic reasons, relatively little coal is “refined” or processed to convert it into cleaner fuels. (The majority is burned in large installations such as electricity power stations, and where restrictions on atmospheric emissions from these very large-scale producers of sulfur dioxide apply, the exhaust gases are washed or otherwise treated.) In some installations coal is gasified by partial oxidation to produce fuel gas or synthesis gas for chemical processing, and considerable tonnages of coal still go into the production of coke and byproduct fuel gas for use in steelmaking and other activities. In both cases, the sulfur appears as hydrogen sulfide in the fuel gas, and as ammonium sulfides in sour water [57].

6.2. Hydrogen Sulfide Removal from Gases

In no case is hydrogen sulfide a desirable constituent of gas streams. It is corrosive to metals, highly toxic, and very offensive smelling, and when burned produces sulfur dioxide, which possesses somewhat similar attributes. It is also a strong poison for many catalysts. It must therefore be separated from any gas stream that is to be burned as a fuel or used as a feed for a chemical process. Because of the corrosive and toxic hazards, it must be removed before it is piped over any distance, i.e., sour natural gas must be processed at the wellhead.

Because hydrogen sulfide has few industrial uses and is inherently dangerous, once it has been separated from other useful constituents of the gas mixture it is normally converted into a more useful form of sulfur. It can be burned to give sulfur dioxide and water and converted into sulfuric acid in a special type of sulfuric acid plant designed to handle moist feed gas; however, the product of choice is usually elemental sulfur, which is cheaper and easier to transport than sulfuric acid. The Claus process operates continuously and performs best under stable operating conditions. Therefore, any gas-purification process used to abstract feed gas for a Claus plant must operate continuously. Particularly in refineries, where a large number of independent process units contribute to the raw fuel gas, the composition and flow of the raw gas may fluctuate suddenly and widely. The hydrogen sulfide removal process must be capable of accommodating such fluctuations, although it is not possible to prevent the fluctuations from having some effect on the Claus feed gas flow rate and composition.

Three main types of continuous process are used for separating hydrogen sulfide from gas mixtures:

1. Direct conversion processes
2. Chemical solvent processes
3. Physical solvent processes

The first group includes wet oxidation and “wet Claus” processes. In the former, represented by the well-proven Stretford process and a number of variations, including Lo-Cat, hydrogen sulfide is absorbed into a solution which oxidizes it to elemental sulfur. This is separated physically, and the oxidizing capability of the solution is restored by blowing air through it. In the solution, the hydrogen sulfide-containing gas is mixed with stoichiometric amounts of sulfur dioxide, and passes

into a solvent in which they react to form sulfur, which is insoluble and is removed in molten form. These processes do not produce a Claus plant feed gas, and are mainly intended for processing relatively dilute hydrogen sulfide gas streams.

The chemical and physical solvent processes regenerate the hydrogen sulfide in a form acceptable in a Claus plant. The raw gas, under superatmospheric pressure, is fed into the bottom of an absorption tower and meets a countercurrent stream of cold scrubbing solvent or chemical scrubbing solution. Desulfurized gas leaves the top of the absorber. The rich solution from the absorber is warmed, depressurized, and fed into the top of a desorption column. In the chemical solvent process, the solution has to be stripped with steam to decompose the weakly bound compound formed between the hydrogen sulfide and the active constituent of the scrubbing solution. The steam is generated by passing solution from the boot of the regeneration column through a reboiler heated by low-pressure steam, and reintroducing it into the column, whereupon steam flashes off. In the physical solvent processes, much of the dissolved gas comes out of solution when the liquor is depressurized, and considerably less steam is used in the reboiler.

There are essentially two main groups of chemical solvent processes. One is based on aqueous solutions of alkanolamines (Fig. 8), including monoethanolamine (MEA), diethanolamine (DEA), diisopropanolamine (DIPA), methyldiethanolamine (MDEA), and diglycolamine (DGA). The other is based on hot aqueous potassium carbonate solutions containing additives to improve absorption performance and inhibit corrosion. These include the Catacarb, Benfield, Giammarco – Vetrocoke, and Alkazid processes.

Physical solvent processes (Fig. 9) include Selexol, using the dimethyl ether of poly(ethylene glycol) as solvent, Fluor Solvent (propylene carbonate), Purisol (*N*-methylpyrrolidone), Rectisol (methanol), and Sepasolv MPE (oligo(ethylene glycol) methyl isopropyl ethers). A hybrid physical/chemical process, Amisol, uses a solution of MEA and DEA in methanol.

Most hydrocarbon gases contain carbon dioxide as well as hydrogen sulfide, in proportions which depend on the origin of the raw gas. Like hydrogen sulfide, CO_2 is acidic, and is always removed to some extent in the absorption tower. To what extent this is desirable depends principally on the use to which the desulfurized gas is to be put, and this has to be taken into account in the choice of process and the composition of the solvent or scrubbing solution. In cases where the raw gas has a high CO_2 : H_2S ratio and it is necessary to remove the CO_2 to very low residual levels, a one-stage acid gas removal process may produce an acid gas with too high a CO_2 content (more than 80 vol %) for a Claus plant to handle efficiently. In that case, a two-stage process can be employed, using selective scrubbing agents, the first to remove only carbon dioxide for separate disposal, and the second to remove the remainder of the carbon dioxide and all the hydrogen sulfide. In such a system, both stages may employ a physical solvent, or the first may be physical and the second chemical, or both stages chemical.

The choice of process is further complicated by the nature and concentration of minor constituents in the raw gas, some of which may be important to remove together with the hydrogen sulfide (e.g., carbonyl sulfide, carbon disulfide, and thiols), and others which are less desirable to absorb, either because they degrade the scrubbing liquor or because they impair the efficiency of the Claus plant (e.g., ammonia, hydrogen cyanide). The choice of acid gas separation process is far from straightforward [57-59].

Direct Conversion Processes (Liquid Redox). The criteria mentioned here are not hard and fast rules, but merely indicate when a process should be considered:

1. Low Sulfur Rate. Consider using one of the liquid redox processes if the total amount of H_2S to be removed is equivalent to or less than an elemental sulfur rate of 5 t/d.
2. High CO_2 : H_2S Ratio. The point where the CO_2 : H_2S ratio is high enough to make one of the liquid redox processes economically attractive is usually below 5 % H_2S in the acid gas.
3. Problems. Common problems in liquid redox processes in the oil and gas industry include sulfur plugging and off-color sulfur [60].
4. General. All liquid redox sulfur recovery processes have the same three basic steps: absorption of the H_2S in an aqueous alkaline solution; reaction of absorbed H_2S with a metal complex, forming elemental sulfur; and reoxidation of the metal complex by air sparging.

Before reaction with H_2S, the metal is in either the +5 or the +3 oxidation state, and is reduced to +4 or +2 by the reaction. Reoxidation returns the metal to the higher oxidation state, completing the cycle. Two processes are described. The first (Stretford) employs vanadium as the primary catalyst interacting with the sulfur species; the second (Lo-Cat) is iron-based.

Stretford (Fig. 10). The Stretford process, the first liquid redox process, has been available since 1959. The original patents have expired and many companies can supply Stretford. The original developer was the North Western Gas Board (now British Gas). Stretford uses vanadium as the primary catalyst for the sulfur reaction and anthraquinone disulfonic acid (ADA) to catalyze oxygen transfer in the regeneration of the reduced vanadium. The Stretford process embodies a wealth of experience with liquid redox processing, both with respect to the variety of applications and the amount of operating time.

Figure 10. The Stretford process

a) Absorber; b) Pump tank; c) Delay tank; d) Slurry tank; e) Oxidizer(s); f) Filter/centrifuge; g) Melter/autoclave

Lo-Cat (Fig. 11). Lo-Cat is a chelated iron liquid redox process that was commercialized by ARI in the late 1970s and has achieved considerable market success since the late 1980s, especially in smaller units. Solution compositions are maintained by regular additions of iron, two proprietary chelates, a biocide, and a surfactant to ensure that the sulfur sinks to the bottom of the oxidizer, where it is removed as a slurry. This eliminates the need for a separate pump tank for the lean liquor. Typical plants have iron concentrations of 500 – 1500 g/m^3, determined by trade-offs between pumping costs and chemical costs. Applications where gas streams contain relatively high H_2S concentrations, such as regenerator acid gases from amine treatment, can use the ARI autocirculation unit, consisting of a single, liquid-filled vessel that replaces the absorber, reaction tank, and oxidizer. Solution circulation is achieved via fluid density differences [61].

Figure 11. The Lo-Cat process

Other liquid redox processes, include Unisulf (Unocal), Sulfolin (Linde) — both vanadium-based processes — and SulFerox (Shell Oil and Dow Chemical), which is an iron-based process.

6.3. History of the Claus Process

More than 100 years ago, the Claus sulfur recovery process was introduced as a means of disposing of hydrogen sulfide generated in the recovery of ammonium sulfate from gasworks ammoniacal liquor. Later, it was extended to process hydrogen sulfide from the LeBlanc soda ash process. Today, a modification of the original process is the basis of hundreds of sulfur recovery units worldwide, with individual capacities up to 2000 t/d, or more. They process hydrogen sulfide from a variety of sources; some comes from the chemical industry, but a large majority is produced in the processing of fossil hydrocarbon fuels and coal.

In the original process, the Claus reaction was carried out in a single step over a catalyst (Fig. 12). Because the heat of reaction was dissipated by radiation alone, sulfur yields of 80 – 90 % were possible only if the hydrogen sulfide space velocity was low. Processing capacity was not significantly increased by installing cooling coils within the catalyst bed, nor by recycling cooled waste gas through the reactor [62]. It was not until the 1930s that IG Farbenindustrie in Germany introduced a revolutionary development which gave improved efficiency at much higher space velocities and also allowed waste heat to be recovered as steam. This consisted of separately burning one-third of the hydrogen sulfide in a flame with the stoichiometric amount of air to convert it completely to sulfur dioxide, cooling the hot gases in a waste heat boiler, and introducing them, with the remaining two-thirds of the hydrogen sulfide, to the catalytic reactor at 200 – 300 °C

Figure 12. The Claus process

$$H_2S + 3/2\,O_2 \rightarrow SO_2 + H_2O$$

$$2\,H_2S + SO_2 \rightarrow 3/x\,S_x + 2\,H_2O$$

This was later modified so that all the hydrogen sulfide, with the stoichiometric amount of air, was passed through the

flame and waste heat boiler, followed by a sulfur condenser [57].

Because a major proportion of the sulfur was formed in the flame zone and removed in a condenser, the loading on the catalytic stage was reduced, and the conversion efficiency was correspondingly raised. In this form, the process was able, in a single stage, to convert hydrogen sulfide in concentrations of ca. 15 % or more to sulfur, with a conversion efficiency of 92 – 94 % at space velocities of 250 – 300 m^3 H_2S per h m^3 catalyst. This version has become known as the *modified Claus process* (Fig. 13).

Figure 13. The modified Claus process

The efficiency is raised by adding one, two, or three further stages, in which the gases leaving the sulfur condenser of the previous stage are reheated and passed through another catalytic reactor, followed by another sulfur condenser. However, plants operating on this principle are usually referred to simply as Claus plants. It is interesting to note that the original Claus process (under the name “direct oxidation”) has become of interest again as a method of dealing with hydrogen sulfide streams that are too weak for processing by the modified process.

Despite the enormous accumulated experience in design and operation of Claus plants, the process is inherently difficult to maintain at full efficiency, yet environmental authorities in many parts of the world have set strict emission limits. Under completely stable conditions, the process can operate consistently at its design efficiency, but any perturbation may lead to a quite substantial loss of efficiency. The problem is partly due to the fact that the chemical reactions involved do not go to completion. Fluctuations in the proportions of air and hydrogen sulfide upset the balance between hydrogen sulfide and sulfur dioxide, and whichever is in excess passes through the plant unchanged. Since the exhaust gas is always incinerated to destroy hydrogen sulfide this leads to an increase in sulfur dioxide emissions. Variations in the temperature in the catalytic reactors also reduce efficiency. These may result from a change in either the flow or the composition of the acid gas. Maloperation of an upstream process can result in the appearance of impurities in the acid gas, which can have a deleterious effect on the catalyst or otherwise affect the performance of the plant.

As environmental and safety regulations have become more demanding, it has become necessary to recover sulfur at high efficiency from gas streams which, formerly, were considered too lean or too impure for the process, and would have been incinerated and discharged to the atmosphere.

The German TA Luft demands sulfur recovery rates of 97 % for recovery units with a sulfur capacity ≤ 20 t/d, 98 % for units with capacity 20 – 50 t/d, and 99.5 % for units of capacity ≥ 50 t/d.

As the chemical reactions involved in the Claus process do not go to completion, these high sulfur recovery rates are impossible to reach without the aid of special tail gas units.

6.4. Chemistry of the Claus Process

The chemistry of the Claus process is much more complicated than the simple equations given earlier suggest. This is partly due to a variety of side reactions between the sulfur- containing species and other components of the acid gas stream, such as carbon dioxide, methane, ammonia, and nitrogen from the air, and partly due to the existence in equilibrium of several molecular forms (S_2 – S_8) in the elemental sulfur vapor [63].

Although there are a number of reactions in the conversion of hydrogen sulfide to sulfur, the overall conversion can be represented by the equation:

$$H_2S + 1/2\,O_2 \rightarrow 1/x\,S_x + H_2O$$

This is, in fact, a chemical equilibrium between the forward reaction of hydrogen sulfide and oxygen to sulfur and water vapor, and the reverse reaction. The rate of forward reaction in an equilibrium of this type is roughly proportional to the product of the molar concentrations of hydrogen sulfide and oxygen, while the rate of the reverse reaction is proportional to the product of the molar concentrations of sulfur and water vapor. As the partial pressure *p* of each component is directly proportional to its molar concentration, the reaction rates are proportional to products of the partial pressures of the reacting species. At a given temperature, the rate of forward reaction is:

$$k_1\left(p_{H_2S}\right)\left(p_{O_2}\right)^{1/2}$$

and that of the reverse reaction is:

$$k_2\left(p_{S_x}\right)^{1/x}\left(p_{H_2O}\right)$$

where k_1 and k_2 are the rate constants for the two reactions at that temperature. As the hydrogen sulfide and oxygen react, their partial pressures decrease, while those of sulfur and water vapor increase; the forward reaction slows down

and the reverse reaction speeds up, eventually reaching a point at which their rates are equal:

$$k_1\left(p_{H_2S}\right)\left(p_{O_2}\right)^{1/2} = k_2\left(p_{S_x}\right)^{1/x}\left(p_{H_2O}\right)$$

Thus:

$$k_1/k_2 = K = \left(p_{S_x}\right)^{1/x}\left(p_{H_2O}\right)/\left(p_{H_2S}\right)\left(p_{O_2}\right)^{1/2} \quad (1)$$

The system is then in equilibrium and there is no apparent further change. The relation k_1/k_2 between the two rate constants is the equilibrium constant K. The values of k_1 and k_2 are profoundly influenced by temperature, though not to the same extent, so the equilibrium constant is also temperature dependent, as is the conversion efficiency.

Conventional modified Claus plants use air as the source of oxygen, and although nitrogen is essentially inert in the reaction, it dilutes the reacting gases, and therefore lowers their partial pressures. The first real study of the thermodynamics of the H_2S – O_2 – S – H_2O equilibrium was performed in 1953 by GAMSON and ELKINS [64], who produced a curve expressing the temperature dependence of the calculated equilibrium conversion of a stoichiometric mixture of pure hydrogen sulfide and air to elemental sulfur (dashed line in Fig. 14) [65].

Figure 14. Equilibrium conversion of hydrogen sulfide to sulfur

Pure H_2S, stoichiometric air, 101 kPa, no sulfur removal – – – –, S_2, S_6, S_8 only [64]; . . . . ., S_2, S_6, S_8 only, recent data; ——— all S_x (S_2 – S_8), recent data

At that time, only the species S_2, S_6, and S_8 were known to exist, but since then S_3, S_4, S_5, and S_7 have been shown to be significant in certain temperature ranges (Fig. 3) [65]. Later studies [65], [66], using more up-to-date thermodynamic data and taking the existence of these species into account, have produced revised curves (dotted and solid lines in Fig. 14).

The left-hand region of the curves represents the equilibrium between H_2S and O_2. As the partial pressure of each component is proportional to its molar concentration in the gas mixture, for a given mass of sulfur, the higher the molecular mass of a species, the lower its molar concentration and, therefore, the lower its partial pressure (1 mol S_8 = 2 mol S_4 = 4 mol S_2). As Figure 14 shows, the proportion of S_8 falls with increasing temperature in favor of S_6, S_7, S_5, and, especially, S_2, and therefore the partial pressure of sulfur increases very rapidly with temperature, promoting the reverse reaction.

This effect tails off above ca. 550 °C, by which point the majority of the sulfur is S_2, and the equilibrium sulfur concentration begins to rise again, because a significant proportion of the hydrogen sulfide is beginning to decompose into its elements. This is the main mechanism by which sulfur is produced in the sulfur furnace.

When the hot gas from the burner is cooled, the sulfur concentration at first drops to the minimum represented in Figure 14, as the dissociated hydrogen and sulfur recombine, and then rises along the right-hand portion of the curve, as the oxidation of hydrogen sulfide progresses. However, as the temperature is lowered, the reaction becomes progressively slower until, below about 350 °C, it is too slow to be of practical use. At this temperature, the best theoretical yield (assuming the system has reached equilibrium) is only about 80 – 85 %. The function of the catalyst in a Claus plant is to extend the lower end of the temperature range over which the reaction takes place at a satisfactory rate to the lowest possible temperature so as to attain the highest possible conversion. The catalyst has no influence on the ultimate position of the equilibrium, only on the rate at which it is attained. Since the position of the equilibrium is a function of the partial pressures of the individual components of the gas, if the partial pressure of any one of them is disturbed, the values of the rest will adjust so as to bring the value of Equation (1) back to K. It is not possible to increase conversion efficiency by using excess oxygen, because although a great proportion of the hydrogen sulfide reacts, it forms sulfur dioxide rather than sulfur. Conversion is, however, favored, if the hydrogen sulfide is highly concentrated, and it is further increased if the nitrogen content of the combustion air is reduced or eliminated altogether. Because water is one of the products, a high moisture loading in the feed gas has a detrimental effect on conversion efficiency.

A fortunate characteristic of the reaction system is that one of the products — sulfur — is much less volatile than any of the other constituents, and can therefore be removed by condensation. This reduces its partial pressure considerably, so that if the remaining gases are reheated and passed over a catalyst, they react again to produce more sulfur. Furthermore, since the sulfur loading of the reaction gases is reduced at each stage, the succeeding catalytic stage can be run at progressively lower temperature without risk of sulfur deposition on the catalyst. This is the principle on which the design of practical Claus plants is based [57].

6.5. Claus Plant Configurations

Figure 15 shows the two main process configurations which are in use for processing acid gases in Claus plants.

Figure 15. Modified Claus process configurations

A) Straight-through (rich feeds); B) Split-flow (lean feeds)

Straight-Through Configuration. All of the acid gas is passed through the reaction furnace and waste heat exchanger. A significant amount of sulfur is produced in the furnace, and removed in the waste heat exchanger and in the condenser before the gas enters the first catalytic converter. The amount of sulfur condensed in the waste heat exchanger depends on the pressure of the steam produced in the waste heat exchanger, and on the gas temperature at the outlet of the waste heat exchanger. The straight-through configuration is used for feed gases containing H_2S at ca. 40 mol % or more.

When the hydrogen sulfide content of the feed gas is below ca. 40 mol %, the flame temperature in a straight-through Claus plant is too low to destroy satisfactorily any carbon or ammonia compounds present in the acid gas. The sulfur produced may be discolored and there may be a risk of plugging the sulfur lines in the “cold” part of the Claus plant.

However, with acid gas and/or air preheaters upstream of the combustion furnace, or with oxygen instead of air for the partial oxidation of the hydrogen sulfide, acid gases with H_2S levels of 20 mol % and even lower can be processed.

Split-Flow Configuration. Acid gases containing H_2S at ca. 20 – 40 mol % can be processed in a split-flow configuration, in which part of the acid gas is fed directly to the first catalytic converter, and the remainder is burned in the combustion furnace. In theory, two-thirds of the acid gas may be bypassed this way, and in that extreme case essentially no sulfur is produced in the furnace, because one-third of the hydrogen sulfide is burned completely to sulfur dioxide [57]. If the acid gas contains ammonia or other contaminants, it cannot be operated in the split-flow configuration, because these contaminants are also present in the bypassed portion. However, in processing an ammonia-free acid gas and a separate ammonia-containing feed gas (e.g., from a sour water stripper containing only a small amount of hydrogen sulfide compared with that in the acid gas) this ammonia-containing gas can be totally processed to the burner and only “clean” acid gas is bypassed to the first catalytic converter.

6.6. The Claus – Oxygen Process

Operators of Claus plants are increasingly confronted with the problem of improving the throughput of existing plants. This problem has arisen from the processing of crude oils of higher sulfur content and from more stringent regulations calling for further desulfurization of certain products. Apart from higher hydrogen sulfide volumes, wider fluctuations in the concentration of the Claus feed gas are experienced, especially when several gas scrubbing units feed one Claus plant.

As the process gas volume is the main criterion for high throughput, and the hydrogen sulfide content of the Claus feed gas determines the temperature in the reaction furnace, the use of oxygen offers a solution to the partial combustion problem. If this operation mode is applied to cover temporary peaks and to overcome periods of low hydrogen sulfide concentration in the Claus feed gas, the oxygen demand is reasonable, and in many cases where oxygen is available within the plant, this demand can be met at low capital cost. The distribution grid of known oxygen suppliers has meanwhile become so dense that oxygen storage/evaporation equipment can be made available [67].

In a normal plant, air is introduced into the system to supply the oxygen necessary for reaction; a considerable volume of inert gas, primarily nitrogen, is also passed through the system. However, if the oxygen content is increased, by replacing some or all of the air with pure oxygen, the volume of inert material passing through the system is substantially reduced or virtually eliminated.

The advantages claimed for oxygen enrichment mostly stem from the reduced nitrogen content of the gas stream. One effect is that, as the degree of enrichment increases, so too does the temperature in the reaction furnace, and it is possible to treat much leaner feeds in the straight-through process configuration. Without modification, the increase in oxygen content is limited to ca. 28 %. Simulations confirm that the use of oxygen does not significantly increase the overall sulfur recovery efficiency. Theoretically, a 0.1 % increase in a three-stage Claus plant is possible.

There are now three types of technology for using oxygen in Claus plants:

1. A special burner (the Lurgi multipurpose OxyClaus burner)
2. A special burner and an additional recycle blower (the COPE process)
3. An additional special burner, combustion chamber, and waste heat boiler (the BOC process)

The Lurgi Multipurpose OxyClaus Burner. In the early 1980s, Lurgi developed a multipurpose burner (Fig. 16) that can be operated with air, air and oxygen, or pure oxygen, without shutdown. Changeover can be done from the control room, either fully automatically or manually, ensuring optimum oxygen consumption. Oxygen is burned with part of the Claus gas while the remaining Claus gas is combusted with the reaction air flow. This means that an extremely hot oxygen flame is produced, enclosed by a colder air/Claus gas flame. In the core of the oxygen flame, decomposition of hydrogen sulfide to hydrogen and sulfur with reduced H_2O formation takes place simultaneously with the reduction of carbon dioxide to carbon monoxide. The oxygen liberated by reduction of the carbon dioxide reacts in turn with the hydrogen sulfide to form sulfur dioxide.

Figure 16. The Lurgi multipurpose OxyClaus burner

The decomposition reactions:

$$H_2S \rightarrow H_2 + 1/2\,S_2$$

$$CO_2 \rightarrow CO + 1/2\,O_2$$

$$H_2O \rightarrow H_2 + 1/2\,O_2$$

are strongly endothermic, and provide for temperature control in the Claus reaction furnace. Gas recycling for temperature reduction in the reaction furnace is unnecessary, even at elevated hydrogen sulfide concentration in the feed gas and with pure oxygen operation.

The Lurgi burner is also designed to combust H_2S acid gas and NH_3 acid gas, and ensures almost complete combustion of ammonia without additional energy consumption. To prevent serious plugging in the “cold” part of the Claus plant, the NH_3- containing gases have to be burned at a temperature of at least 1300 –1350 °C in air.

This occurs in a central burner muffle, which is also used to combust fuel gas for heating, when the plant is started up or shut down. Around the central burner muffle a number of individual H_2S acid gas burners with concentric process air and oxygen supplies are arranged. The oxygen lances for the individual burners are equipped with individual temperature control.

In 1985, the first Lurgi burner went on stream in a refinery in Germany, operating with ca. 50 % oxygen. The plant has been in continuous oxygen operation up to now without experiencing any problems.

By 2005, more than 32 plants equipped with the Lurgi OxyClaus burner were in successful operation. The Lurgi OxyClaus burner is the most widely used oxygen technology for Claus plants using an oxygen content of > 30 % [68].

The COPE Process. Offered by Air Products & Chemicals, Allentown, Pennsylvania, who developed it with Goar, Allison & Associates, Tyler, Texas, the COPE (Claus oxygen-base process expansion) process was the response to Conoco's need to increase capacity because of changing feedstocks. With the COPE process it is possible to operate with pure oxygen. Such a high degree of enrichment is attainable mainly because of two design features.

First, a recycle stream is used to keep the furnace temperature within safe limits; second, a special burner is used. A flow diagram for a typical three-stage Claus sulfur recovery unit after installation of the COPE process is shown in Figure 17 [69].

Figure 17. The COPE sulfur recovery unit

a) Reaction furnace with waste heat boiler; b) Steam reheater; c) Converter; d) Condenser; e) Air blower; f) Recycle blower

The recycle, which is the heart of the process, allows the temperature rise in the reaction furnace to be moderated by the recycle of inert components and reaction products, specifically nitrogen, carbon dioxide, and water vapor.

The recycle of inert components increases the pressure drop of the furnace – waste heat boiler – first condenser section. However, the reheater – catalytic converter – condenser sections of the plant experience a reduced pressure drop due to lower volumetric rates. The combination of oxygen enrichment and gas recycling thus permits a large increase in throughput. Increasing the feed capacity of a Claus plant with this oxygen technology results in the production of additional sulfur. Frequently, rundown lines are generously sized when the plant is designed and these do not represent a bottleneck. If replacements are necessary they generally do not represent a major expense compared with other parts of the unit.

Revamps of two sulfur recovery units at Conoco's Lake Charles refinery and two at Champlin Refinery's Corpus Christi refinery were completed in 1988. In the latter installation, debottlenecking was achieved by installing oxygen enrichment without the recycle system, although provision to add this (i.e., full COPE operation) has been made [69], [70].

The BOC Process. Through its Industrial Process Division, Shipley, West Yorkshire, BOC has supplied oxygen enrichment technology to several industries. As well as conventional oxygen enrichment technology (adding up to ca. 25 % oxygen to the process air feed), BOC has signed an agreement with The Ralph M Parsons Company, Pasadena, California, to market processes that can be operated with either oxygen-enriched air or pure oxygen; the proprietary SURE oxygen-enrichment technology provides cost-effective solutions to this demand.

The conventional configuration involves the addition of a new reaction furnace burner, reaction furnace, and waste-heat boiler upstream of the existing reaction furnace (Fig. 18).

Figure 18. Conventional SURE double combustion configuration reusing existing reaction furnace (RF) and waste-heat boiler (WHB)

Gas effluent from the new waste-heat boiler is routed to the existing reaction furnace, which serves as the second thermal stage. With this configuration the SURE double combustion technology allows the capacity of the sulfur recovery unit to be expanded at considerably lower costs compared to building new air-based sulfur recovery units.

Occasionally, existing reaction furnaces and waste-heat boilers cannot be reused because of original design limitations. In these cases, a two-pass waste-heat boiler with an extended head can be designed in which the extended head serves as the second-stage reaction furnace and the second pass serves as the second waste-heat boiler (Fig. 19). This two-pass waste-heat boiler configuration effectively reduces capital cost and conserves plot space requirement.

Figure 19. Conventional SURE double combustion configuration with new two-pass waste-heat boiler [71]

6.7. Troubleshooting

Operating Claus plants is straightforward — provided that the feed is according to specification, steam tracing is good, all ratio controllers are set correctly, heat exchanger tubes are not plugged, and so on. It may happen that some of these assumptions are not justified. This Section describes some problems which may occur in Claus units.

Incorrect Air Ratio. Using too much air is the easiest way to lose conversion. For optimum conversion, the H_2S : SO_2 ratio is 2 : 1. The ratio is measured in the tail gas from the final condenser. Sulfur plants are best run on closed-loop tail gas analyzer control. In practice, other methods are often needed to adjust the air supply to the reaction furnace.

If air flow to the reaction furnace is much too high, SO_3 is formed in the incinerator and forms a white plume. A yellowish plume indicates insufficient air to the front end of the sulfur plant.

The incinerator temperature can also be used to indicate the air required in the reaction furnace. A high incinerator temperature, coupled with low incinerator fuel consumption, indicates insufficient air supply to the reaction furnace. Alternately, if large amounts of fuel are required to maintain incinerator temperature, the air supply to the reaction furnace is in excess.

If the tail gas analysis shows SO_2 equal to H_2S, one can cut sulfur losses by 5 % just by reducing the air supply.

COS and CS_2. The presence of hydrocarbons and CO_2 in the acid gas promotes the formation of COS and CS_2 in the reaction furnace. These compounds can significantly contribute to SO_2 in the incinerator. One can essentially destroy both COS and CS_2 by operating the first reactor at an outlet temperature of 320 – 340 °C, so that they are hydrolyzed to H_2S and CO_2. An increase in SO_2 emissions, accompanied by a lower than normal first reactor inlet temperature, is likely due to COS and CS_2.

When to Change Catalyst. A common question put to an operating engineer by the sulfur plant supervisor is “Do we need to change catalyst during the unit turnaround?” With a little luck, this question may be asked before the plant is shut down.

If pressure drop is normal through the catalyst beds, this is a tough question. With adequate instrumentation, one can obtain a vertical temperature profile through the first catalyst bed, and then develop data to make a firm decision. For catalysts in good condition, ≥ 90 % of the heat of reaction is released in the top 200 mm. If catalyst activity is impaired, the reaction is shifted down the bed.

Damage to catalyst and reduced conversion can be a consequence of many other factors besides lost activity: carbon deposits, leaking condenser tubes, damaged support screens, sulfuric acid formation, operation at the sulfur dewpoint. These problems are, however, invariably associated with increasing pressure drop. The most common cause of lost catalyst activity is reversible — sulfur deposits due to low bed temperatures.

Carbon Deposits. The following chain of events illustrate the problem. Light hydrocarbons accidentally enter the amine regenerator, along with the rich amine. The hydrocarbon is stripped overhead. Some condenses in the reflux drum; the rest remains as a vapor and is transferred, along with H_2S, to the sulfur plant. Ten times more air is needed to oxidize 1 mol propane than 1 mol H_2S. When the light hydrocarbon vapors reach the sulfur plant, carbon black is produced in the reaction furnace:

$$C_3H_8 + 2\,O_2 \rightarrow 3\,C + 4\,H_2O$$

The carbon black is deposited on the top of the first catalyst bed. Gas flow is restricted, and a high pressure drop results. Providing sufficient combustion air to the reaction furnace could have prevented this.

The operating engineer can determine if increasing pressure drop is due to carbon accumulation on the catalyst by making the following observations:

1. Is the SO_2 concentration in the sulfur plant tail gas very low (less than 1000 mL/m^3) ? Low SO_2 is a sign of insufficient air supply to the reaction furnace.
2. Are light hydrocarbons accumulating in the amine regenerator reflux drum?

Having determined that the catalyst bed is plugged with carbon, the engineer seeks to correct the situation. Over a period of time, the carbon reacts with SO_2. Unfortunately, this reaction proceeds slowly at low temperature. Maximizing reactor inlet temperature and SO_2 levels can help. Significant (10 %) reductions in pressure drop can take weeks. Shutting down and changing the catalyst may be more practical. The best solution to this incident would have been to keep carbon black from forming in the first place.

There is only one reliable way to prevent such situations — liquid hydrocarbons must be separated from the rich amine upstream of the amine regenerator.

Leaks. A tube leak in the high-pressure steam boiler can lead to major problems. The high-pressure water can erode the metal, and the flow of water into the hot gas stream may increase rapidly.

Water quenches the sulfur-bearing gases, sulfur precipitates on the catalyst. This stops gas flow through the plant. The worst thing that can happen to a sulfur plant is a crash shutdown. Plants should be cleared of sulfur by burning natural gas instead of H_2S before a shutdown, continuing natural gas firing until the amount of liquid sulfur overflowing from the seal legs is reduced to a trickle. When the plant shuts down suddenly, precipitating sulfur solidifies in the catalyst beds, and flow through the unit cannot be re-established.

An alert operating engineer must identify boiler tube leaks before it is too late. A gradual increase in pressure drop is an early warning sign. When this happens, it is vital to check for low steam production rates from the high-pressure boiler. Another tip-off is a low gas outlet temperature from the boiler. If both steam production and outlet temperature are low and pressure drop is high, the plant must be shut down. There is a tube leak.

Water (steam) leaks also reduce conversion of H_2S to sulfur. The Claus equilibrium is shifted to the left as the H_2O partial pressure increases [72].

6.8. Optimization of Sulfur Recovery Units by Use of Analyzers

In the thermal stage of the sulfur recovery process, one-third of the H_2S gas is burned to form SO_2:

$$3H_2S + 1.5\,O_2 \rightarrow 2\,H_2S + SO_2 + H_2O \qquad (1)$$

and the remainder reacts subsequently with SO_2 to form S in the thermal and catalytic stages:

$$2\,H_2S + SO_2 \rightarrow 3/n\,S_n + 2\,H_2O \qquad (2)$$

This is often referred to as the modified Claus process.

Sulfur recovery efficiencies in conventional Claus plants vary from 94 to 97 % for a two-stage plant, and from 96 to 98 % for a three-stage plant. Higher sulfur recoveries are difficult to obtain mainly for the following reasons:

- The Claus reaction is an equilibrium reaction and thus H_2S and SO_2 conversion is limited.
- Process water produced in the Claus reaction hinders conversion and limits total sulfur recovery.
- The critical H_2S/SO_2 ratio of 2/1 is difficult to maintain in a practical manner.

The choice of process configuration (straight-through, split-flow, sulfur recycle, and direct oxidation) largely depends on the acid-gas composition and flow rate, impurities in the acid gas, past experience of designers, and economics. Most sulfur recovery plants are based on the modified Claus process.

Poor operation of the sulfur recovery unit (SRU) may lead to:

- Poor sulfur quality which makes selling difficult and lowers the selling price.
- Soot formation in the furnace or to hydrocarbon breakthrough, which leads to plugging of catalyst beds and further to limited throughput because of high differential pressure.
- Shortened catalyst lifetime due to deactivation/sulfating.
- Fouling in catalyst bed structure, heat exchangers, mesh pads, and sulfur drains.

The most important parameter after flows and temperatures is feedback control of the air/acid gas ratio, which

automatically controls the air to the furnace to stoichiometric optimum and compensates for other O_2-consuming reactants such as hydrocarbons and ammonia, often with fluctuating concentrations.

The use of tail-gas analyzers to assist in the control of combustion air to acid gas ratios in Claus sulfur recovery plants is standard in the industry. The plant tail gas is analyzed by UV spectroscopy and a corresponding output signal is determined. This signal is proportional to the percentage change required in the combustion air to provide stoichiometric concentrations of the principal reactants H_2S and SO_2. When the process is optimized and the correct stoichiometric concentrations of H_2S and SO_2 are achieved, the feedback signal — normally referred to as air demand A — is zero, and no change in combustion air is required. The simplified air demand equation is:

$$A = F([H_2S] - R_{op}[SO2])$$

where F is the plant-specific gain factor, $[SO_2]$ the concentration of SO_2, $[H_2S]$ the concentration of H_2S, and R_{op} the operating ratio (typically 2). At stoichiometric concentrations of H_2S and SO_2 (H_2S:SO_2 = 2:1) A becomes zero regardless of the factor F when R_{op} is 2. When the plant-specific gain factor is established for a particular process, the units of air demand become “per cent change required in process air”, that is, a computed air demand of +1.5 % indicates that the process has 1.5 % excess in air.

To achieve optimum performance of the Claus sulfur plant, the air demand should be kept near zero. Independent analysis of just H_2S and SO_2 is not sufficient to ensure accurate results. The sample gas, obtained from the sulfur plant waste or tail gas stream, also contains other sulfur species: COS, CS_2, and sulfur vapor. These species, while not necessarily required as outputs, must be analyzed and corrected for, as they interfere with the H_2S and SO_2 analysis. Requirements for H_2S, SO_2 analyzer are:

- Fast response
- Efficient sulfur-vapor suppression
- Trouble-free sample system
- Robust industrial design
- Accurate measurement of components
- Reliable and easy to maintain system
- Self-explanatory user interface
- Low installation cost and cost of ownership
- Competent, reliable, and customer-oriented service support

The latest generation of H_2S/SO_2 analyzers, e.g., those of the company Pier Enterprises, are based on UV spectrophotometers with broadband source/spectral detection having full spectrum analysis, high resolution (0.2-nm pixel resolution), and interferences calculated with precision for all SRU gas matrices. Wide dynamic range and very fast response are further advantages of this technology [73].

7. Increased Sulfur Recovery

7.1. Selective Oxidation

Section The Claus – Oxygen Process mentioned the use of oxygen as an important improvement in Claus technology. Another improvement is the introduction of super-catalysts in the Superclaus and Selectox processes [74].

7.1.1. *The Superclaus Process, the Euroclaus Process*

The Dutch companies Comprimo and VEG-Gasinstituut, in cooperation with the University of Utrecht, have developed a new version of the Claus process, called the Superclaus process, which increases the sulfur recovery rate of a Claus plant to > 99 %. Two versions have been developed: Superclaus-99 and Superclaus-99.5.

The Superclaus process produces elemental sulfur from H_2S gas, and is characterized by the use of a new selective oxidation catalyst in the last reactor stage. The process has the following features:

1. Overall sulfur recovery up to 99.5 % without tail gas treatment
2. Application in new as well as existing Claus plants
3. Low investment and utility costs
4. Continuous catalytic process without water condensation
5. Use of a new catalyst for direct selective oxidation of H_2S to sulfur

The new catalyst has the unique ability to convert H_2S with excess oxygen into elemental sulfur at > 90 % efficiency. Moreover, high water concentrations in the process gas hardly influence the conversion [75].

Superclaus-99. The conventional Claus process employs a series of steps consisting of: (1) sulfur conversion; (2) cooling, sulfur condensation and removal; and (3) process gas reheating before the next conversion step. Since the Claus equilibrium is involved in each conversion step, a close approximation to equilibrium is reached in the final stage. The

standard Claus process has several limitations which are due to: failure to reach equilibrium; increasing water content of the process gas with decreasing concentration of hydrogen sulfide and sulfur dioxide; formation of COS and CS_2 in the flame, which requires hydrolysis in the first Claus reactor; and the demand for exact control of the air : acid gas ratio. The Superclaus process (Fig. 20) incorporates two new concepts. These are a less sensitive and more flexible air : acid gas control, and a new catalyst for selective oxidation of hydrogen sulfide directly to sulfur, rather than to sulfur dioxide.

Figure 20. The Superclaus-99 process

a) Combustion chamber; b) Waste heat boiler; c) Condenser; d) Reactor; e) Selective oxidation reactor; f) Incinerator

The acid gas feed is burned in the thermal stage in such a manner that the tail gas leaving the second Claus reactor stage contains 0.8 – 1.5 mol % hydrogen sulfide. The burning step is operated under oxygen-deficient conditions so that the $H_2S : SO_2$ ratio in the furnace is much higher than the conventional value of 2 : 1. As the process gas passes through the various stages, the presence of surplus hydrogen sulfide suppresses the concentration of sulfur dioxide in the gas. As a result, the second Claus reactor outlet may contain concentrations of 0.8 mol % H_2S and 0.05 mol % SO_2. In the Superclaus stage, the gas leaving the second-stage Claus sulfur condenser is reheated and mixed with surplus air before it enters the Superclaus reactor. Here, an essentially nonequilibrium oxidation reaction occurs:

$$H_2S + 1/2\,O_2 \rightarrow 1/^n\,S_n + H_2O$$

The new Superclaus catalyst is the key to this oxidation step. Over 85 % of the hydrogen sulfide is oxidized directly to sulfur, and very little sulfur dioxide is formed. The catalyst consists of a carrier on which metal oxides are supported. The catalyst is chemically and thermally stable and has good mechanical strength. It has a specific surface area < 20 m^2/g, compared with the Claus catalyst value of 300 – 325 m^2/g. The Superclaus catalytic stage is followed by a final sulfur condenser and coalescer vessel, and then the incinerator/stack.

Superclaus-99.5. The Superclaus-99.5 process consists of a thermal stage, two or three catalytic Claus stages, a hydrogenation stage, and a selective H_2S oxidation stage (Fig. 21).

Figure 21. The Superclaus-99.5 process

a) Combustion chamber; b) Waste heat boiler; c) Condenser; d) Reheater; e) Reactor; f) Hydrogenation reactor; g) Selective oxidation reactor; h) Gas cooler; i) Incinerator

The thermal stage and the catalytic Claus reactors are operated conventionally, with an $H_2S : SO_2$ ratio of 2 : 1. The combustion air to the burner is controlled by a conventional H_2S/SO_2 tail gas analyser. As only H_2S is oxidized to elemental sulfur, other sulfur components, e.g., SO_2, COS, and CS_2, must be converted first to H_2S in the hydrogenation reactor. The gas from the hydrogenation reactor is cooled to the optimum inlet temperature of the selective oxidation reactor. The control of the $H_2S : SO_2$ ratio of 2 : 1 is less critical than for standard Claus operation. Fluctuations in the feed gas composition to the unit are absorbed by the excess air supplied to the selective oxidation stage.

The total recovery with two or three catalytic Claus reactors is 99.2 – 99.7 %, depending on the oxidation efficiency [76].

The Euroclaus process (Fig. 22) is an extension of the Superclaus process. It exhibits enhanced efficiency of the selective oxidation section and in particular a reduction of the SO_2 level in the Claus product gas.

Figure 22. The Euroclaus process

The product gas from the Claus section contains some SO_2, which is not converted in the Superclaus reactor. The amount of SO_2 in Claus tail gas is usually in the range of 500 – 1200 vol ppm wet. This amount depends on the catalyst activity of the preceding Claus reactor and the amount of H_2S in the process gas (ratio H_2S to SO_2).

The recovery loss due to this Claus SO_2 is normally in the range of 0.15 – 0.35 % sulfur recovery for process gas from a second Claus reactor. Conversion of the bulk of this SO_2 by H_2 and CO in the Claus process gas according to:

$$SO_2 + 3\,H_2 \rightarrow H_2S + 2\,H_2O$$

$$SO_2 + 2\,H_2 \rightarrow 1/8\,S_8 + 2\,H_2O$$

$$SO_2 + 2\,CO \rightarrow 1/8\,S_8 + 2\,CO_2$$

will reduce these SO_2 losses to below ca. 0.10 % sulfur recovery.

A special challenge is the suppression of simultaneous COS formation from CO and S vapor. CO is normally present in the Claus process gas in the range of 0.2 – 5.0 vol % wet. At higher CO levels, say 1 vol % or more, this COS formation may be in the range of 500 vol ppm and cannot be prevented. An additional bottom layer of hydrolyzing catalyst which is active at 220 – 230°C has proven to be effective for bulk conversion of COS and also SO_2 according to [77]:

$$COS + H_2O \rightarrow CO_2 + H_2S$$

$$2\,COS + 2\,CO \rightarrow 2\,CO_2 + 3/8\,S_8$$

7.1.2. *The Recycle Selectox Process*

The Recycle Selectox process (Fig. 23) was developed by Union Oil Company of California (UNOCAL) and The Ralph M. Parsons Company. The process was developed mainly for sulfur recovery from lean acid gas streams, typically containing 40 mol % H_2S or less. The Recycle Selectox process is an all-catalytic process, which eliminates the need to burn one-third of the H_2S in a furnace. The incoming acid gas feed is preheated, mixed with recycle gas, and then with process air in the same stoichiometric amount used in the conventional Claus process. The hot, mixed gases enter the Selectox catalyst bed, where a selective oxidation of H_2S to SO_2 occurs in the upper few inches of the bed, and the Claus reaction occurs (to about 80 % completion) in the remainder. The hot gases exit the Selectox converter and enter a sulfur condenser where they are cooled, and about 65 – 70 % of the sulfur present in the feed is condensed and recovered. Effluent gases from the condenser are split, with a portion of the stream being returned to the Selectox bed inlet as recycle gas. This recycle of mainly inert gas serves to dilute the incoming feed and prevents the bed outlet temperature from becoming too high for the carbon steel structural materials in the plant. The rest of the stream (net forward flow) is reheated and passed to one or more Claus stages, the final tail gas being incinerated and vented to the atmosphere.

Figure 23. The Recycle Selectox process

HTM = Heat-transfer medium

Overall sulfur recoveries of 94 – 97 % are common. The Recycle Selectox process is appropriate for sulfur recovery from relatively small, lean acid gas streams [78].

7.1.3. *The Once-Through Selectox Process*

The Once-Through Selectox process (Fig. 24) is used for acid gas feed streams containing less than ca. 5 mol % H_2S. No recycle blower is required. The incoming feed is preheated, and the correct amount of air injected. The mixture enters the Selectox stage (first reactor) in the autoignition temperature range. From that point forward, the discussion given earlier for the Recycle Selectox process applies, with the exception of the recycle flow relationships. Typically, two Claus stages and a final incineration stage follow the first Selectox reaction stage.

Figure 24. The Once-Through Selectox process

HTM = Heat-transfer medium

With an acid gas feed of 1 – 5 mol % H_2S, an overall sulfur recovery of 85 – 90 % can be expected [79].

7.2. Tail Gas Treatment

7.2.1. *Sub-Dewpoint Processes*

Sulfur recovery of the modified Claus process is limited by the operating temperatures in the catalytic reactor stages. The lower the operating temperatures, the higher the recovery rates.

However, operating the Claus reactors at lower temperatures, i.e., below the sulfur dewpoint, involves adsorption of sulfur on the catalyst, which has to be regenerated after a certain operation time.

So-called sub-dewpoint processes have been developed, all of which use the more favorable equilibrium at lower temperatures. These processes can be simply described as an extension of the conventional modified Claus process.

All are cyclic processes, adsorbing the sulfur produced on the catalyst. The catalyst is regenerated before it becomes significantly deactivated.

In the beginning, around 1970, the maximum achievable sulfur recovery rate with the modified Claus plus sub-dewpoint

process, was ca. 98.7 –99.2 %; in the mid-1990s, sulfur recovery rates of 99.0 – 99.9 % became possible.

The best known sub-dewpoint processes are:

1. The Sulfreen processes
2. The CBA processes
3. The MCRC processes

Common to them all is the ability of the catalyst, not only to adsorb the H_2S and SO_2 from the process gas and act as catalyst for the Claus reaction, but also to have an affinity for the sulfur produced. Product sulfur is adsorbed on the walls of the pores in the catalyst. This reduces the partial pressure of sulfur vapor and allows additional H_2S and SO_2 to react in accordance with the reaction equilibrium [80].

7.2.1.1. *The Sulfreen, Hydrosulfreen, and Doxosulfreen Processes*

Claus plants, as a rule consisting of one thermal and two or three catalytic stages, generally convert 94 – 98 % of the sulfur compounds in the feed gas into elemental sulfur. To increase the sulfur recovery rate in order to reduce SO_2 emissions, the Sulfreen processes have been developed by Lurgi, Germany; and Elf Aquitaine, France. The first Sulfreen plant was started in 1970 in Lacq, France; by 2005, more than 50 had been built.

A wide degree of flexibility is possible with the Sulfreen processes [81]. Three versions are available:

1. The Sulfreen process, based on an extension of the Claus process, where residual H_2S and SO_2 in the Claus tail gas reacts on a fixed catalytic bed at a temperature below the sulfur dewpoint. At such a low temperature (125 – 150 °C) equilibrium conversion of H_2S and SO_2 is nearly complete and sulfur recovery of 99.5 % or more can be achieved.
2. The Hydrosulfreen process, which overcomes the limitation of the Sulfreen process due to COS and CS_2 present in the Claus tail gas. It is implemented by converting these compounds to H_2S in a catalytic pretreatment step upstream of the Sulfreen reactor. This process can achieve an overall sulfur recovery of 99.5 – 99.7 %.
3. The Doxosulfreen process converts residual H_2S and SO_2 from the upstream Sulfreen step with oxygen into elemental sulfur. A sulfur recovery rate of 99.9 % can be obtained.

Sulfreen. The Sulfreen process (Fig. 25) is based on the well-known Claus reaction in which H_2S and SO_2 in the process gas are catalytically converted to elemental sulfur.

Figure 25. The Sulfreen process

a) Sulfreen reactors; b) Condenser; c) Blower; d) Heater; e) Incinerator and stack

The process operates in the gas phase, the operating conditions being those at which the tail gas leaves the upstream Claus plant. The catalyst, arranged in fixed beds, is activated alumina, with properties similar to those of Claus catalysts.

The tail gas from the Claus plant is passed at a temperature of 120 – 140 °C through one of the two reactors where, by means of the catalyst, most of the H_2S and SO_2 are converted to elemental sulfur and adsorbed on the catalyst.

The sulfur-loaded catalyst can be regenerated by using part of the Claus tail gas. The regeneration gas is heated in an indirectly fired heater. Hot flue gas from thermal incineration or directly fired heaters can also be used.

The sulfur in the hot regeneration gas is recovered in the sulfur condenser. After subsequent cooling of the catalyst bed with purified tail gas, the reactor is again ready to be switched to adsorption.

Hydrosulfreen. The Hydrosulfreen process (Fig. 26) is based on the pretreatment of the Claus tail gas by hydrolysis of COS and CS_2 to H_2S, and direct oxidation of H_2S to sulfur:

Figure 26. The Hydrosulfreen process

a) Hydrolysis/oxidation reactor; b) Heater; c) Sulfreen reactors; d) Incinerator and stack; e) Heat exchanger; f) Condenser; g) Blower

$$COS + H_2O \rightarrow CO_2 + H_2S$$

$$CS_2 + 2\,H_2O \rightarrow CO_2 + 2\,H_2S$$

$$2\,H_2S + O_2 \rightarrow 2\,S + 2\,H_2O$$

These reactions are performed by bringing the Claus tail gas directly into contact with an activated titanium oxide catalyst.

In a second process step, the remaining sulfur compounds in the process gas are removed as in the Sulfreen process.

The tail gas from the upstream Claus unit (temperature ca. 130 °C) is heated in tail gas preheaters to ca. 200 – 250 °C, and passed to the hydrolysis/oxidation reactor where the temperature rises to ca. 250 – 300 °C, owing to the exothermicity of the reactions. For gas heating, a gas – gas heat exchanger in the waste gas downstream of the final incinerator, or directly fired heaters can be used.

Doxosulfreen. The Sulfreen process is based on the Claus equilibrium, which at 130 – 140°C lies almost completely on the product side. At the outlet of the Sulfreen reactor the concentrations of H_2S and SO_2 are already greatly lowered, and the rather high concentration of water vapors favors the back reaction to a certain extent. Hence, the potential of the Claus reaction is almost exhausted. Further desulfurization in the Doxosulfreen process is therefore based on direct oxidation of H_2S with oxygen at temperatures similar to those of the Sulfreen process. The upstream plant is operated with a small excess of H_2S so that the tail gas of the Sulfreen step contains ca. 2500 ppm H_2S and 250 ppm SO_2. A controlled amount of air is mixed with the gas (O_2/H_2S ratio approximately twice the stoichiometric ratio), and the gas is passed through the catalytic reactor. On the catalyst surface, with the excess of hydrogen sulfide, the Claus reaction is further completed according to:

$$10\,H_2S + SO_2 \rightarrow 3\,S + 2\,H_2O + 8\,H_2S$$

The remaining hydrogen sulfide is oxidized to elemental sulfur:

$$2\,H_2S + O_2 \rightarrow 2\,S + 2\,H_2O$$

Depending on the type of catalyst, a small amount of sulfuric acid is formed by oxidation of SO_2.

The products are adsorbed in the pore system of the catalyst. Initially activated carbon was used as catalyst, leading to the name Carbosulfreen process. However, experience with gases of different origin and composition has shown that in some cases other catalysts such as impregnated alumina are advantageous. Therefore, Doxosulfreen was chosen as a general name for these direct oxidation processes.

The plant essentially consists of two reactors for pretreatment of the Claus tail gas (Sulfreen stage) and two reactors filled with direct oxidation catalyst (Fig. 27). One of these reactors operates in the adsorption mode and the other in the regeneration mode. The regeneration loop comprises the sulfur condensers as well as the blower and the heater for the regeneration gas. Both stages are regenerated simultaneously. The tail gas from the Claus plant is passed through the reactor containing the Sulfreen catalyst at 130 – 140°C. The gas leaving the Sulfreen unit is cooled to ca. 125°C before adding the air for oxidation. The tail gas from the Doxo reactor is passed to the incinerator, where the very small amounts of sulfur components are converted to SO_2.

Figure 27. The Doxosulfreen process

a) Sulfreen reactors; b) Doxosulfreen reactors; c) Intercooler; d) Incinerator and stack; e) Condenser; f) Blower; g) Heater

Regeneration of the catalyst is carried out with tail gas from the Claus plant, which is heated to 300 – 330 °C by a special gas heater or by heat exchange with hot flue gas from the incinerator. This gas contains 1 – 2 % H_2S, so any sulfuric acid formed during adsorption is reduced to elemental sulfur. The gas is cooled to ca. 125 °C in a sulfur condenser, and the elemental sulfur is drawn off in liquid form. The regeneration gas is recycled. Following desorption, the reactors are cooled to operating temperature again [83].

7.2.1.2. *The CBA Process*

The first commercial installation of the Amoco cold bed adsorption (CBA) process was commissioned in September 1976 at Amoco's East Crossfield sulfur recovery facilities in Alberta, Canada.

By 1993, approximately 22 additional facilities have shown the process to be readily capable of meeting the robust processing requirements of sulfur recovery.

The CBA process offers a viable solution to the 98 – 99.5 % sulfur recoveries necessary to meet regulatory requirements in many parts of the world. The process is typically accomplished in two or more CBA catalytic reactors: one being used for the low-temperature sulfur formation reaction, with sulfur adsorption on the catalyst, while the other is being regenerated.

Regeneration is carried out by feeding hot gas to the process through the reactor to heat the catalyst, and to desorb and vaporize the sulfur.

The effluent gas from the first reactor in the Claus unit, which is operated at high temperature, is used for regeneration. After regeneration, the CBA reactor has to be cooled by means of a cool gas stream, such as CBA feed gas. When the catalyst has been adequately cooled, the converter is reused for the low-temperature Claus reaction, with adsorption of sulfur on the catalyst.

A number of equipment configurations and flow-sheets have been developed.

Four-Reactor CBA/Rotate R 1, R 2, R 3, R 4. The four-reactor CBA/rotate R 1, R 2, R 3, R 4 process configuration (Fig. 28) is similar to the majority of the four-reactor designs completed and operating to date. The feed gas to the CBA system is supplied by the front-end facilities, e.g., thermal reactor, waste heat boiler, thermal condenser, and reheater.

Figure 28. Four-reactor CBA/rotate R 1, R 2, R 3, R 4

Gas flows in sequence through the four reactors. The first reactor in the series operates as a Claus reactor, and is also simultaneously being regenerated. The remaining three reactors operate as CBA reactors. Once the reactor operating as the Claus reactor is regenerated and cooled, it is switched to the tail CBA position. A condenser is provided downstream of each reactor, but only one reheat gas system is required.

Of all the possibilities, this process configuration is capable of achieving the highest levels of sulfur recovery. The equipment is relatively simple, but careful design is required to balance the expected sulfur loading rate with the catalyst regeneration and process cooling capability.

Three-Reactor CBA/Rotate R 1, R 2, R 3. One of the major enhancements to the original four-reactor system is the three-reactor multiple CBA bed configuration (Fig. 29). This improved configuration consists of a single Claus reactor followed by two sub-dewpoint CBA reactors. Overall sulfur recovery approaching that of a conventional four-reactor system can be attained.

Figure 29. Three-reactor CBA/rotate R 1, R 2, R 3

Front end, thermal reaction; back end, Claus/CBA catalytic converter

In the three-reactor CBA/rotate R 1, R 2, R 3 configuration, the first reactor operates continuously in the Claus mode, and the second and third reactors operate in the CBA mode. The Claus reactor is operated at a high temperature to destroy carbonyl sulfide and carbon disulfide and to provide regeneration gas. The adsorption – regeneration CBA cycle is accomplished in two CBA reactors, functioning in cyclical fashion between the lead position and tail position. In each step, effluent gas from the lead position reactor is fed to a two-stage CBA condenser before being fed to the tail-position reactor. The two-stage CBA condenser functions both as a gas cooler and as a sulfur condenser, generating steam and also using boiler feedwater as coolant. The gas outlet temperature of the CBA condenser is controlled by the flow of boiler feedwater to the second stage CBA condenser. Low-pressure steam is generated in the first-stage CBA condenser, using boiler feedwater preheated in the second stage. Effluent from the tail-position CBA reactor is routed directly to incineration. The lead CBA reactor is in either a regeneration or adsorption mode, while the tail CBA reactor is always in an adsorption mode. Regeneration is accomplished by introducing hot Claus reactor effluent directly to the lead CBA reactor. The stripped sulfur is subsequently recovered in the CBA condenser. Once the lead CBA reactor is regenerated, the lead bed is cooled by directing the Claus reactor effluent through the Claus condenser, before flowing to the lead CBA reactor. The final step in the cycle is the adsorption – adsorption operation. In this case the lead and tail CBA reactor positions are switched [80].

7.2.1.3. *The MCRC Process*

The MCRC process is a sub-dewpoint Claus process that achieves sulfur recovery efficiencies of 99 % or more. The licensor is Delta Projects, Canada; the first MCRC sub-dewpoint Claus plant began operation in 1980.

The MCRC process is designed with either three or four catalytic converters. A higher conversion of H_2S to sulfur is achieved by operating the last converter in a three-converter plant, or the last two converters in a four-converter plant, at temperatures below the dewpoint of the sulfur produced. As the reaction proceeds and sulfur is adsorbed into the catalyst, the catalyst becomes deactivated and requires periodic regeneration or sulfur desorption and vaporization. This is accomplished on-line by using the full forward flow of the sulfur plant process stream. It is not necessary to take the converter out of the process flow for off-line regeneration, as is the case for other sub-dewpoint Claus processes, so the MCRC process requires less equipment and fewer switching valves and associated piping.

The four-converter MCRC process described below achieves sulfur recoveries as high as 99.5 %, the three-converter process can sustain average recoveries above 99 %.

Four-Converter Process. The four-converter MCRC process recovers more sulfur than the three-converter process, but more significantly, the dip in recovery during the bed switch which occurs in the three-converter process is essentially eliminated.

In the four-converter process, the last three converters alternate sequentially in the second, third, and fourth converter positions, which are in regeneration mode. In Figure 30, converters 2, 3, and 4 occupy positions 2, 3, and 4. Gas from condenser 2 is reheated in a gas – gas exchanger, and enters converter 2 to regenerate the catalyst bed. Sulfur that is desorbed and vaporized exits with the regeneration gas stream and enters condenser 3 where it condenses and separates.

Figure 30. The four-converter MCRC process, operating step 1

Vapor from condenser 3 enters converter 3 where the first stage of sub-dewpoint conversion occurs. Most of the sulfur produced is adsorbed into the catalyst, while the remainder leaves the converter with the gas, and condenses and separates in condenser 4. Condenser 4 discharges vapor into converter 4, where the second and final stage of sub-dewpoint conversion occurs. Virtually all of the sulfur produced is adsorbed into the catalyst, and the remaining vapor cools in condenser 5, and passes to the tail gas incinerator.

When the catalyst in converter 4 reaches a certain sulfur loading, and the catalyst in converter 2 has been regenerated, the converter positions change successively (Fig. 31). Converter 2, which was in the second position (regeneration mode), is now in the third position (first sub-dewpoint mode), and converter 3, which was in the third position (first sub-dewpoint mode), is now in the fourth position (second sub-dewpoint mode), and finally, converter 4, which was in the fourth position (second sub-dewpoint mode), has switched back to the second position (regeneration mode).

Figure 31. The four-converter MCRC process, operating step 2

Figure 32 illustrates the completion of the cycle. Converter 2 has switched from the third position to the fourth position, and converter 3 has switched from the fourth position back to the second position, while converter 4 has switched from the second position to the third position.

Figure 32. The four-converter MCRC process, operating step 3

To summarize, in the four-converter MCRC process, each of the last three converters switches sequentially through three alternate operating steps: regeneration, first sub-dewpoint, and second sub-dewpoint. These three steps constitute a complete cycle. When a converter completes its second sub-dewpoint step, it switches into the regeneration step to begin a new cycle. Most of the production of sulfur that occurs by sub-dewpoint Claus conversion occurs in the converter that operates in the third position (first sub-dewpoint mode). Hence, the temperature rise in this converter is relatively large. The amount of conversion that can occur in the fourth converter position (second sub-dewpoint mode) is less than for the third position, and therefore the corresponding temperature rise is low, < 3 °C. Thus, the operating temperature in the last converter is lower for the four-converter MCRC plant than for the three- converter plant, and there is a corresponding increase in recovery.

The four-converter MCRC process is inherently stable during a bed switching. There is essentially no dip in recovery because the two sub-dewpoint beds in series act as a buffer that damps the impact of the bed switch [84].

7.2.2. *Processes Working on Reduced Tail Gases*

7.2.2.1. *The SCOT and Super-SCOT, and "SCOT-like" Processes*

The SCOT Process. The Shell Claus off-gas treating (SCOT) process (Fig. 33) was introduced in the early 1970s as an attractive process, combining the well-known ADIP treating technique with a new development.

Figure 33. The Shell SCOT process

a) Inline burner; b) SCOT reactor; c) Quench tower; d) SCOT absorber; e) SCOT regenerator (stripper); f) Reboiler; g) Waste heat exchanger

In the SCOT process, nearly all sulfur compounds leaving the Claus unit are converted into H_2S over a hydrotreating catalyst (Co – Mo or Ni – Mo) at ca. 280 – 300 °C. Nearly all sulfur compounds (other than H_2S), e.g., SO_2, COS, CS_2, and elemental sulfur are converted into H_2S. Claus tail gas is heated via an in-line burner which at the same time can produce reducing gas (H_2 and CO) by substoichiometric fuel combustion. Alternatively, if available, an external source of reducing gas can be applied. In this case, another possibility is to heat the tail gas in a gas – gas heat exchanger against incinerator off-gas, or in a heat exchanger using steam to heat the Claus tail gas. The hot H_2S-containing gas leaving the reactor is cooled in two stages: first a gas cooler, producing low-pressure steam, and then a quench column, in which most

of the water in the gas is condensed and sent to a sour-water stripper.

The cooled process gas is subsequently treated in an amine absorber. A selective wash solvent is used for H_2S absorption, while most of the CO_2 in the gas passes through. The SCOT off-gas, typically containing 250 – 500 mL/m^3 H_2S, is routed to an incinerator.

The amine can subsequently be regenerated by stripping with steam or, alternatively, its carrying capacity, which is only partially employed in SCOT, can be fully utilized by feeding to an intermediate tray in the fuel gas or mainstream absorbers. The concentrated acid gases are recycled to the Claus inlet [85].

The Super-SCOT Process. The Super-SCOT version (Fig. 34 [86]) has been developed to achieve an H_2S concentration of 10 mL/m^3 or a total sulfur content < 50 mL/m^3.

Figure 34. The Super-SCOT process

a) Reheater; b) Reactor; c) Quench column; d) Absorber; e) Regenerator; f) Gas cooler

The process is based on two-stage stripping, optionally in combination with a lower lean solvent temperature; these features can be applied separately or in combination.

In order to reach a specific solvent leanness (H_2S/amine), a specific steam rate (steam/solvent) is required. A leaner solvent will result in a lower H_2S concentration in the SCOT off-gas. However, in order to lower the H_2S concentration in the SCOT off-gas, it is necessary to regenerate the entire solvent flow to this lower leanness level.

This has led to the idea of applying two-stage regeneration in which part of the amine solvent flow is more deeply stripped. The super-lean solvent is routed to the top tray of the absorber, whereas the semi-lean solvent enter half way up the absorber.

The solubility of H_2S in amine solvents is increased when the temperature is lowered. A lower amine temperature results in a lower H_2S partial pressure of the solvent, which enables reduction of the H_2S concentration in the SCOT off-gas. The objective is to lower the total sulfur content to less than 50 mL/m^3 as well as to reduce steam consumption by 30 % compared with the standard SCOT unit. Both options have been applied successfully.

Now, after expiration of the SCOT patent some other processes, known as “SCOT-like processes' are on the market, such as Lurgi's LTGT (Lurgi Tail Gas Treating) and the HCR (High Claus Ratio) process from Siirtec Nigi.

7.2.2.2. *The Sulften Process*

The Sulften system (Fig. 35) is an amine-based tail gas reduction process, developed by Ford, Bacon & Davis, and Union Carbide which reduces the H_2S content of the vent gas to less than 10 mL/m^3.

Figure 35. The Sulften process

a) Sulften combined reactors; b) Sulften contact cooler; c) Sulften absorber; d) Solution cooler; e) Solution exchanger; f) Sulften stripper; g) Sulften stripper reboiler; h) Condenser; i) Reflux accumulator; j) Sulften reactors heater; k) Sulften reaction products cooler; l) Rich pump; m) Lean pump

The process consists of two sections: the reaction section and the absorption – desorption section. The reaction section provides for the conversion of sulfur species to H_2S. Tail gas enters the process and is heated to the optimum temperature for the hydrolysis reactions to take place. The heated gas is then reacted over a fixed bed of hydrolysis catalyst. After these reactions are complete, hydrogen is added to the gas stream, which is adjusted to the optimum operating conditions for the hydrogenation reactions. The hydrogenation reactions take place over a second fixed bed of catalyst. The residue gas contains essentially no sulfur species except H_2S.

The reactor effluent is indirectly cooled by generation of low-pressure steam in a waste heat boiler. Further cooling is achieved by quenching the gas with water in a packed or trayed tower prior to the absorption – desorption section.

The absorption – desorption section consists of two towers, an absorber where the H_2S is removed from the vent gas stream, and a stripper to release the absorbed gases for recycle to the Claus unit. The treated gas is either released to the atmosphere or passed to an incinerator, depending on the emission standards required in the country where the plant is located.

The Sulften solvent is a proprietary methyldiethanolamine-based solvent which can reduce the H_2S content of the absorber vent gas to less than 10 mL/m^3, while absorbing approximately 10 % of the CO_2 present in the absorber feed [87].

7.2.2.3. *Solvents for Regenerative H_2S Removal*

Many of the solvents used in regenerative hydrogen sulfide removal processes absorb both hydrogen sulfide and carbon dioxide. However, increased energy costs and the desire for improved sulfur plant operation have made selective gas sweetening (i.e., preferentially absorbing hydrogen sulfide while “slipping” carbon dioxide into the treated stream) more attractive, and several selective solvents are now commercially available [88].

To guarantee sulfur recovery rates of 99.95 % or better for Claus plus tail gas units, special “performance” solvents are now on the market.

The development of alkanolamine solvents for acid gas treating is summarized in Figure 36. Monoethanolamine (MEA), diethanolamine (DEA), and, to a lesser extent, diglycolamine (DGA) have been used for total acid gas removal. With the dramatic increase of energy costs in the early 1970s, improved sulfur plant operation and selective sweetening were needed.

Figure 36. Evolution of gas-treatment solvents

Methyldiethanolamine (MDEA), a tertiary amine, eventually became the most common selective solvent, owing to its resistance to degradation and low tendency to cause corrosion.

The latest development in amine technology was the introduction of performance solvents, based on tertiary amines. Proprietary additives are combined with the tertiary amine to give even greater selectivity and lower energy consumption. Additives can also be used to remove organic sulfur compounds such as carbonyl sulfide [89].

The Super-SCOT process (Section The SCOT and Super-SCOT, and “SCOT-like” Processes) uses a tertiary amine-based solvent, guaranteeing < 10 mL/m^3 H_2S and < 50 mL/m^3 total sulfur components in the absorber off-gas.

The solvent used in the Sulften process (Section The Sulften Process) is a proprietary MDEA-based solvent which can reduce the H_2S content in the gas downstream of the absorber to < 10 mL/m^3. Exxon Research and Engineering has developed Flexsorb SE and SE Plus solvents which are aqueous solutions of a sterically hindered amine, specifically developed to have high hydrogen sulfide selectivity. For low-pressure service, such as sulfur plant tail gas cleanup, H_2S levels of ca. 150 mL/m^3 can be achieved with Flexsorb SE, or 10 mL/m^3 with Flexsorb SE Plus [88].

Another performance solvent, UCARSOL Solvent HS-103 (Union Carbide) is also able to achieve H_2S levels < 10 mL/m^3 in the treated off-gas stream.

7.2.2.4. *The BSR/Selectox Process*

The BSR/Selectox tail gas cleanup (TGCU) process (Fig. 37) is utilized downstream of a Claus unit to improve the overall sulfur recovery to typically 98.5 – 99.2 % [79]. Claus tail gas is heated by mixing with hot gases containing hydrogen and carbon monoxide, produced by a reducing gas generator. This gas mixture then passes through a bed of catalyst for reduction of essentially all sulfur components in the tail gas to H_2S. Effluent gases from this reactor are partially cooled by flowing through a waste heat boiler, and then cooled still further by a contact condenser which lowers the water saturation temperature of the gases to just above ambient temperature. Cooling and water removal are necessary to assure maximum conversion of H_2S to sulfur in the oxidation reactor. The hydrogenated tail gas normally contains about one-third water vapor. Removal of most of this water is essential to the process, since water opposes the Claus reaction to sulfur.

Figure 37. The BSR Selectox sulfur recovery process

The condensate is pumped to a sour water stripper for H_2S removal. The cooled, saturated gases from the contact condenser are heated by exchange with steam to ca. 160 °C, and mixed with the stoichiometric air needed for the oxidation of H_2S to sulfur, which occurs in the second fixed-bed catalytic reactor containing Union Oil's proprietary Selectox-32 catalyst. Premium quality sulfur is obtained by cooling the effluent gases from the direct oxidation reactor to ca. 130 °C, using another waste heat boiler. The cooled gases are mixed with ca. 50 % excess air, and sent to incineration [90].

7.2.3. ***Processes Working on Oxidized Tail Gas***

7.2.3.1. *The Wellman – Lord Process*

The Wellman – Lord process (Fig. 38) was developed in the United States in the late 1960s. The first commercial plant went on stream in 1970. In the following 12 years, 30 plants were built in the United States and Japan; later, Wellman – Lord activities switched to Europe, where 6 plants had been installed by 1993.

Figure 38. Wellman – Lord absorption – regeneration circuit

The Wellman – Lord process is a regenerative process. It involves in removing highly dilute sulfur dioxide from the flue gas in the absorption section, and turning it into rich SO_2 gas in the regeneration section. The recovered gas is directly processed into the end-products: elemental sulfur produced by the Claus process, concentrated sulfuric acid, or liquid SO_2. As the recovered SO_2 gas is already of high purity, these end products meet the highest quality standards.

The process employs sodium sulfite solution in the absorption – regeneration circuit. The solution selectivity removes SO_2 from the flue gas, and sodium bisulfite is formed. During the absorption and subsequent desorption processes, the pH of the solution varies only slightly.

The absorption reaction is reversed in the regeneration section. By thermally regenerating the product solution in an evaporator – crystallizer, the absorbed SO_2 is released again and, after removing the water vapor by cooling, it emerges as a concentrated gas containing 95 % SO_2 by volume. The resulting condensate is used to redissolve sodium sulfite crystallized during regeneration. The fresh solution is ready again for SO_2 absorption, and the circuit is closed.

Figure 39 shows a simplified diagram of the Wellman – Lord system. The concentrated, pure SO_2 gas recovered in the regeneration section can easily be converted into elemental sulfur.

Figure 39. Wellman – Lord flow diagram

For SO_2 reduction the Redotherm process is used. The gas mixture from the Redotherm unit is further processed, together with the refinery H_2S gases, in a Claus plant. The Claus plant (present in most refineries) only needs to be extended by a Redotherm reactor upstream of the thermal Claus reactor; installation of a new Claus unit is usually unnecessary. In the Redotherm process, natural gas is preferable for reduction of SO_2, but hydrogen or town gas can also be used [91].

7.2.3.2. *The Clintox Process*

The Clintox process (Figs. 40, 41) can be described as follows. Tail gas from a Claus plant is incinerated as usual. The hot gas from the incinerator is cooled, e.g., by steam generation, heating of the purified gas, and/or by cooling water. The gas is fed to the bottom of a scrubbing column with three different sections. In the first section, the gas is cooled by direct contact with cooling water, and most of the process water is removed. The dewatered gas enters the second section of the SO_2 scrubber through a chimney tray. There the SO_2 is removed down to a residual content which may be < 1 mL/m^3. The purified gas leaves the top of the column after passing through a third step, another water scrubbing section, removing all traces of the solvent from the purified gas. The purified gas is then fed to the stack, usually after heating. The charged solvent is regenerated in a second column. At the top of the regeneration column, an SO_2 fraction is tapped off, which typically contains more than 85 % SO_2 (plus CO_2 and water). This fraction is recycled to the Claus plant, where the SO_2 reacts with the H_2S in the Claus feed and is recovered as elemental sulfur.

Figure 40. Principle of the Clintox process

Figure 41. The Clintox SO_2 recycle process

a) Heater; b) Catalytic incinerator; c) SO_2 scrubber; d) Solvent regeneration

One of its main features is that the Clintox process uses physical scrubbing while the others all use chemical scrubbers. In a physical scrubbing process, the amount of SO_2 in the tail gas has no influence on the amount of scrubbing liquid, so high SO_2 concentrations can be scrubbed at the same cost as minor concentrations. In other words, the efficiency of the

scrubbing increases with increasing SO_2 concentrations in the tail gas, provided there are enough trays in the wash column. This has some positive effects on the Claus tail gas treatment. One is that the physical SO_2 scrubber almost completely absorbs fluctuations in the SO_2 load, short-lived or long-term, e.g., by catalyst deactivation in the upstream Claus unit. This ensures a high overall sulfur recovery rate, even if the upstream Claus unit cannot be operated optimally, e.g., owing to varying Claus feeds. Even then, sulfur recovery > 99.9 % can be achieved as a long-term average, (not just for short, favorable conditions). Claus catalyst aging can be tolerated much longer without reducing sulfur recovery. This reduces operating costs [92].

7.2.4. *Biodesulfurization; Thiopaq Process*

The Thiopaq process, which has been used to sweeten biogas since 1993, has now been further developed to remove H_2S from high-pressure natural gas, synthesis gas, and refinery gas streams. The Shell-Paques/Thiopaq process can offer a safe and cost effective alternative to liquid redox processes and amine/Claus installations with loads up to 45 t/d.

The Thiopaq family of biotechnological processes removes and converts hydrogen sulfide (H_2S) or sulfur oxides (SO_x) from gas streams, aqueous streams, or light hydrocarbons. The process operates under near-ambient conditions using safe, naturally occurring, living microorganisms as catalysts.

Sulfur compounds must be dissolved in an aqueous medium. When gas streams are treated, the gas is scrubbed with an aqueous sodium bicarbonate solution, which is regenerated in the Thiopaq bioreactor and recycled to the scrubber. In the regeneration process elemental sulfur is produced. When refinery spent caustic is treated with Thiopaq, sulfide can be converted to either sulfur or sulfate. Although the treated caustic is not regenerated, it is safe for disposal and light mercaptans are also converted.

The Shell-Paques/Thiopaq process for H_2S removal of gaseous streams offers:

- Replacement for amine treating, Claus recovery, and tail gas treating or liquid redox processes.
- Minimal chemical consumption.
- Gas treatment as well as sulfur recovery.
- 99.99 % H_2S removal for gas streams.
- 100 % conversion of sulfide in the bioreactor with 95 – 98 % selectivity to S^0.
- No deactivation.
- Applicable to H_2S concentrations of 100 ppm to 100 vol % and pressures from 1 – 75 bar. Therefore, direct treatment and amine off-gas treatment are both possible.
- High turndown ratio.

A simplified flow scheme of the Shell-Paques/Thiopaq process is presented in Figure 42.

Figure 42. Thiopaq Process for the treatment of H2S-containing gas streams

In the Shell-Paques/Thiopaq process, H_2S-containing gas is absorbed in an alkaline solution under full pressure (up to 75 bar) in an absorption step. For hydrocarbon-containing gases a tray or packed column is the preferred gas/liquid contactor but gases at low pressures and without hydrocarbons can be directed immediately to the bioreactor. The dissolved sulfide is subsequently oxidized to elemental sulfur in the Thiopaq reactor:

Absorption and hydrolysis of H_2S

$$H_2S(g) + OH^- \rightarrow HS^- + H_2O$$

Biological sulfur formation

$$HS^- + \frac{1}{2} O_2 \rightarrow S^0 + OH^-$$

The caustic that is used to absorb H_2S gas is regenerated during the production of elemental sulfur. Normally less than 3.5 % of the sulfide is oxidized to sulfate. To avoid accumulation of sulfate, a continuous bleed stream from the bioreactor is required and make-up water with some caustic is needed. For installations located in dry areas the discharge of sulfate-containing aqueous streams into the environment may be unwanted.

The bleed stream can be minimized by application of membrane filtration. The membrane filter separates the sulfate ions from the other ions, leading to a sulfate-rich effluent stream. Alternatively, the production of an effluent stream can be avoided by continuously recycling part of the bioreactor content over a sulfate-reducing reductive stage to convert sulfate back to hydrogen sulfide. In 1999, an installation producing 4 t/d H_2S started up using H_2 gas as the reducing agent. By the end of 2000, 16 Thiopaq units treating biogas and one treating vent air had been licensed. In addition, a large pilot-plant testing programme was performed by Shell Global Solutions Int. and Paques Natural Solutions at the gas plant of

BEB in Großenkneten (Germany), where the process was tested for treatment of high-pressure natural gas under a variety of conditions.

Paques Natural Solutions developed the Thiopaq process for biogas applications. Together with Shell Global Solutions the development was extended to (high-pressure) natural gas and syngas applications. Simultaneously, UOP and Paques developed treatment of spent caustic and LPG [93].

7.3. Purification

There is no general method of purifying raw sulfur. The treatment used depends on the nature and concentration of the impurities and on the intended use of the sulfur. Simple mechanical impurities can be removed to some extent by melting and settling, but it is better to filter the molten sulfur in wire mesh filter presses.

7.3.1. *Arsenic and Selenium Removal*

Arsenic and selenium occur principally in sulfur produced from sulfide ores, although arsenic may also be found in sulfur recovered from hydrogen sulfide in direct oxidation processes which use an arsenical scrubbing solution. Arsenic is best removed by treating with alkalis or chlorine. Selenium is resistant to alkali treatment; to remove it the sulfur can be treated with aqua regia.

7.3.2. *Melting of Stretford Sulfur*

The aqueous sulfur suspensions produced by the direct-oxidation type gas-washing process (see Direct Conversion Processes (Liquid Redox).) can be treated by an autoclave process [94].

The suspensions contain ca. 10 % sulfur, the remainder being scrubbing solution. After thickening in a decanting centrifuge to a solid content of 43 – 57 %, the slurry is maintained in a homogeneous state in an agitated vessel, from which it is continuously conveyed to the autoclave by an eccentric screw pump. The upper part of the autoclave is divided by a tightly wound steam-heated heating coil into a central melting zone, containing an agitator, and an annular phase separation zone; there is a space in the bottom of the autoclave for sulfur to collect. The entire vessel is maintained at 140 – 150 °C and 500 kPa to keep the liquid sulfur mobile, and prevent boiling of the solution. The slurry is fed in at the top of the melting zone and flows downwards. The dispersion of liquid sulfur and aqueous scrubbing solution flows upward through the phase separation zone. As the liquid sulfur agglomerates, it falls back into the sulfur collection zone in the bottom of the autoclave. The aqueous phase leaves the vessel at the top, and is flash-cooled by depressurization. Condensate from the flash vessel is reused in the slurry homogenizing vessel or returned to the scrubbing process. The molten sulfur is released from the bottom of the autoclave into a heated sulfur collection tank. Its purity is generally ca. 95 – 98 %. The principal impurities are constituents of the scrubbing solution used in the direct oxidation scrubbing process, e.g., sodium and vanadium salts from the Stretford process [63].

7.3.3. *Degassing of Claus Sulfur*

Liquid sulfur produced in a Claus plant contains some dissolved H_2S and hydrogen polysulfides. When the temperature of the sulfur decreases, the polysulfides tend to decompose and H_2S is released. This may cause a buildup of toxic quantities during sulfur loading and unloading, and a buildup of explosive concentrations in unvented storage tanks or tankers.

For these reasons, it is often desirable to degas molten sulfur; many refineries are legally required to degas the liquid sulfur to an H_2S level < 10 mg/kg.

The solubility of hydrogen sulfide in liquid sulfur is anomalous; more hydrogen sulfide dissolves at high temperature than at low temperature (Fig. 43). This is due to the formation of hydrogen polysulfides, weakly bound polymeric compounds of hydrogen sulfide and sulfur:

Figure 43. Solubility of H_2S in liquid sulfur at 100 kPa H_2S vapor pressure

$$H_2S + (x-1)\,S \rightarrow H_2S_x$$

The concentrations of H_2S and H_2S_x as functions of total H_2S solubility at different temperatures are shown in Figure 44.

Figure 44. H_2S and H_2S_x as functions of H_2S solubility in liquid sulfur at 100 kPa H_2S vapor pressure

Sulfur produced at different stages in a Claus plant has different hydrogen sulfide concentrations; for example, from the thermal stage there may be 500 – 700 mg/kg S, while from a third reactor stage the concentration is only mg/kg S. An average value of 100 – 150 mg/kg S is normally used when designing degassing systems.

Decomposition of Polysulfides. The reaction whereby hydrogen polysulfides, in the liquid phase, decompose to give liquid sulfur and dissolved hydrogen sulfide, is very slow.

$$H_2S_x \rightarrow H_2S + (x-1)\,S$$

Hydrogen sulfide passes into the gas phase by physical desorption. Thus, the degassing of liquid sulfur involves both releasing the dissolved hydrogen sulfide, which can be enhanced by agitating the sulfur, and accelerating the decomposition of the polysulfides. Consequently, it is important to know both the hydrogen sulfide concentration and the $H_2S : H_2S_x$ ratio; whereas most of the hydrogen sulfide is in the form of polysulfides in freshly produced sulfur, in sulfur that is, say, 12 h old, the hydrogen sulfide and polysulfides are in equilibrium (at 150 °C they are present in roughly equal amounts).

To promote the decomposition of hydrogen polysulfides, it is possible to use a catalyst for example the Aquisulf® catalyst.

Hydrogen sulfide released from the liquid sulfur is removed by a sweep gas passed across the surface. Preferably air, but also Claus plant tail gas, nitrogen, or other inert gases can be used. The sweep gas reduces the hydrogen sulfide partial pressure in the gas space above the liquid, thereby accelerating the physical desorption of hydrogen sulfide, which in turn favors the decomposition of polysulfides [95].

Two degassing systems are briefly outlined: the Shell and the ELF/Lurgi Aquisulf processes.

The Shell Sulfur Degasification Process. In the Shell process (Fig. 45), sulfur degassing is accomplished in a section of the normal underground sulfur production pit or in a section of a normal sulfur vessel. The actual degassing takes place in the stripping column (box) where sulfur is vigorously agitated by bubbling air through the liquid sulfur. The stripping column is open at the bottom and the top, and designed so that the sulfur is circulated through the column a few hundred times per hour (sulfur lift principle). The stripping gas used in the column must be air, not N_2, CO_2, Claus tail gas, SCOT off-gas, nor any other gas which contains little or no oxygen. Air is normally supplied as slipstream from the air blower of the Claus plant.

Figure 45. The Shell sulfur degassification process

a) Eductor; b) Sulfur pump; c) Pit; d) Stripping column (box); e) Weir

The presence of oxygen actually lowers the H_2S content of the liquid sulfur, probably by a direct oxidation reaction with some of the dissolved H_2S, to form elemental sulfur. The stripping air, together with an additional flow of air to the vapor space in the pit or sulfur vessel, serves as sweep gas to keep the H_2S concentration in the vapor space below 1.5 vol %. This is well below the “lower explosive limit” of H_2S in air (3.5 vol %). A steam eductor is used to remove the sweet gas, containing the released H_2S, from the pit (or sulfur vessel) and discharge it to the incinerator for disposal. The degassed sulfur product flows over a weir in the pit (or sulfur vessel) to a pumping compartment where it is pumped to product forming or storage.

The ELF/Lurgi Aquisulf degassing process (Fig. 46) consists typically of a concrete pit which is divided in two compartments by a partition wall. The first compartment is equipped with a sulfur recirculation pump and a spraying system, and the second compartment with a sulfur recirculation and a transfer pump also with a spraying system.

Figure 46. ELF/Lurgi Aquisulf degassing process

Sulfur to be processed is routed continuously into the first compartment of the pit. The liquid sulfur is pumped back into the pit by spraying system. Sulfur flows to the second compartment through a defined opening located at the bottom of the

partition wall. Sulfur is sprayed again in the second compartment, where degassing is completed. It is then transferred to storage by the recirculation and transfer pump. A constant level is controlled inside the pit.

From the catalyst dosing system the liquid Aquisulf catalyst in an amount of max. 20 mg/kg sulfur is routed to the degassing pit by means of a catalyst metering pump. To allow quick mixing of the catalyst with sulfur the catalyst is injected at the suction side of each sulfur recirculation pump.

The vapor phase of the pit is swept with air. Sweeping gas flows countercurrently to the liquid sulfur from the second compartment to the first through a defined hole located at the top of the partition wall. The air is routed either to the incineration or to the Claus combustion chamber.

Several safety features are incorporated to ensure that an explosive H_2S/air mixture is not formed in the pit:

- The flushing air flow is measured at the pit inlet. Should this flow be too low, degassing is automatically stopped.
- The H_2S concentration can be measured by an online analyzer.
- In case of high gas temperatures degassing is stopped.
- Fire is extinguished by snuffing steam.
- Explosion doors are installed on the pit roof.

The sulfur temperature must be at least 130 °C in the degassing pit. Depending on temperatures of inlet sulfur and of flushing air, the sulfur pit can be heated by means of low-pressure steam coils installed at the bottom of the pit. For optimal degassing conditions the sulfur temperature should be less than 150 °C. A low sulfur level automatically cuts off recirculation pumps to avoid uncovering of the steam coils and pump impellers.

7.4. Sulfur Management (Lurgi's OmniSulf Process)

Natural gas is the fastest growing primary energy source in the EIA (Energy Information Administration) 2002 forecast, and its use is projected to almost double between 1999 and 2020, providing a relatively clean fuel to meet worldwide energy demand. However, it is essential for all sulfur components and (in part) carbon dioxide to be removed before natural gas is liquefied (LNG), fed to a pipeline, or used as a feedstock for the production of base chemicals such as methanol or fertilizers. OmniSulf comprises technologies from BASF, Zeochem, and Lurgi to meet specifications according to process requirements and/or environmental regulations. It is based on Lurgi's proprietary experience as a technology licensor and engineering contractor.

Natural gas purification consists of four main process units: acid gas removal (AGR), dehydration and mercaptan removal (DMR), sulfur recovery unit (SRU), and mercury removal unit (MRU). This normally results in four different licensors, four sets of liabilities, and numerous interfaces between the involved parties that often give rise to good excuses. If one unit does not work properly, it is quite easy to blame inadequate battery limit conditions or specifications. The exception, however, proves the rule: BASF/Lurgi's “one-stop shop” sulfur management eliminates all the aforesaid constraints. One reason OmniSulf was developed was to raise the overall sulfur recovery rate to 99.5 %, but if the dictated sulfur recovery rate is not that strict OmniSulf can easily be economically adapted to customer requirements. Single-line responsibility is achieved with the following concept:

- One license contract, one overall guarantee and liability, and one transparent license fee.
- Comprehensive basic engineering completed by a single company (Lurgi).
- Tailor-made design to avoid multiplication of internal design margins.

This results in significant Capital expenditure (CAPEX) and Operational expenditure (OPEX) savings. The three partners, BASF, Zeochem, and Lurgi, rank among the leaders in their respective fields:

- OmniSulf can be licensed all over the sales gas and LNG producing world without restrictions.
- It can be designed as a full plant concept (Fig. 47), including sulfur production, but it can also be restricted to single units, for example, fuel gas treatment and acid gas re-injection.

Figure 47. OmniSulf process

The OmniSulf concept shown in Figure 47 encompasses the following proprietary key processes: Acidic components are removed using BASF's aMDEA process (AGR). The cleaned gas is routed to a DMR unit that removes moisture and mercaptans with Zeochem's special 13X zeolite technology. Where necessary, the sweet gas can be further routed to a mercury-removal unit operated with impregnated activated carbon.

The DMR is thermally regenerated at regular intervals. Mercaptans are recovered from the regeneration gas using Purisol technology. The gas can then be fed to the fuel gas system.

All gas streams containing sulfur are routed to a sulfur recovery unit (SRU). Elemental sulfur is produced in the Claus process (CLS, Lurgi Multi-Purpose Burner). A Lurgi tail gas treating and acid gas enrichment unit (LTGT) is connected to the Claus unit to boost sulfur recovery. The sulfur product is then further treated in an Aquisulf degassing process, which

achieves H2S concentrations in sulfur below 10 vol ppm. Vent gases are incinerated before being released to the atmosphere. In the Claus process, Lurgi's Multi-Purpose Burner is used for optimum operation. This unique burner system allows for stoichiometric combustion and therefore complete destruction of mercaptans in the center of the burner, while H_2S is simultaneously converted substoichiometrically as required by the Claus reaction $(2\,H_2S + SO_2 = 3\,S + 2\,H_2O)$. Conversion to elemental sulfur is completed by the reaction between the remaining SO_2 and H_2S in catalytic converters.

Due to the saturated sulfur market, acid gas re-injection is increasingly chosen as a viable alternative. The OmniSulf concept can be tailored for gas re-injection [96], [97].

[Top of Page]

8. Gas-Phase Reduction of Sulfur Dioxide

Elemental sulfur can be recovered directly from gaseous sulfur dioxide by reducing it with gases containing carbon monoxide, hydrogen, or hydrocarbons. It is also possible to reduce sulfur dioxide with solid carbonaceous material, such as coke or coal. The problem is significant in the smelting of nonferrous sulfide ores, where the large amounts of sulfur dioxide raise pollution problems if no market exists near the smelter for sulfuric acid or liquid SO_2. The reduction method can be also used for treating stack gas from power stations; however as the concentration of SO_2 is very low, a sulfur dioxide concentrator is necessary.

Several processes, based both on solid and gaseous reducing agents have been proposed, some of them have been tested in pilot plants, but only a few have been commercialized.

8.1. The Allied Chemicals Process [98], [99]

In the Allied Chemicals process (Fig. 48), the SO_2-containing gas is purified, mixed with natural gas, and preheated. The reduction step consists of one main catalytic reactor and two auxiliary reactors, which are alternatively utilized as regenerators, i.e., one of them is heated by the hot gas from the main reactor, while the other is used for preheating the gas stream to the main reactor. The conversion is carried out at 800 – 1100 °C in two steps. In the first, a portion of the SO_2 in the feed gas reacts with natural gas, yielding a mixture of elemental sulfur, hydrogen sulfide, carbon dioxide, and water vapor, according to the following equation (natural gas shown as methane):

Figure 48. The Allied Chemicals process

a) Hot gas heat exchanger; b) Centrifugal blower; c) Main reactor; d) Auxiliary reactors/regenerators; e) Temperature control bypass valves; f) Four-way valve; g) Sulfur condenser;

$$2\,CH_4 + 3\,SO_2 \rightarrow 1/n\,S_n + 2\,H_2S + 2\,CO_2 + 2\,H_2O$$

Hydrogen sulfide, formed in the first step, reacts in the second step with the remaining SO_2, yielding additional elemental sulfur and water vapor:

$$H_2S + SO_2 \rightarrow 3/n\,S_n + 2\,H_2O$$

After condensing the sulfur, the gas is led to the Claus plant, where the residual sulfur dioxide, hydrogen sulfide, and carbon – sulfur compounds are converted to elemental sulfur.

The process was developed by Allied Chemicals, Morristown, New Jersey, in 1965; it was first commercialized by Falconbridge Nickel Mines during the period 1969 – 1972; several other commercial installations are known.

At present, however, only one plant is in operation: the Buschhaus power plant in Germany, where the process has been converted to continuous mode [100] (Fig. 49). The concentrated SO_2 gas is divided into two streams; one of which is preheated to the starting temperature of the catalytic reaction and conducted into the first reactor. The heat of reaction, is utilized to heat the second stream by mixing both flows. The combined gas flow then passes through the second reactor, where the residual sulfur dioxide is reduced. After the two-step condensation of sulfur, the gas is conducted to the Claus plant.

Figure 49. Modified Allied Chemicals process [100]

8.2. Other Processes with Gas as Reducing Agent

Two older natural gas reduction processes exist, both with one main and two additional catalytic stages, but differing in the temperature of the main reactor: the Asarco process, developed by the American Smelting and Refining Company in the

1940s; and the Texasgulf process, developed in the 1950s. Neither has ever been commercialized [98].

Lurgi has developed two thermal reduction processes, called Redotherm and Redomet, which use hydrogen and natural gas, respectively, as reducing agent [100], [101].

In the Redomet process (Fig. 50), the sulfur dioxide is reduced at 1000 – 1200 °C in a noncatalytic reactor to S_n and H_2S according to the following equations (natural gas shown as methane):

Figure 50. The Redomet process

$$CH_4 + 2\,SO_2 \rightarrow 2/n\,S_n + CO_2 + 2\,H_2O$$

and:

$$2\,CH_4 + 3\,SO_2 \rightarrow 1/n\,S_n + 2\,H_2S + 2\,CO_2 + 2\,H_2O$$

Two Redotherm reactors have been in operation at the OMV refinery at Schwechat, Austria since 1985. Each Redotherm – Claus plant has a sulfur capacity of 90 t/d; a mixture of 90 % hydrogen and 10 % natural gas is used as reducing agent.

8.3. Processes with Coke or Coal as Reducing Agent

Cominco operated a process at Trail, British Columbia, between 1935 and 1940, in which SO_2 gas with some oxygen was passed at 1300 °C through a bed of coke. Coke was charged at the top, and ash was removed on a rotary grate at the bottom of the furnace. The gas, containing CO, CO_2, S_x, and COS was conducted to a catalytic bauxite bed, where the carbonyl sulfide was converted to CO_2 and S_x by addition of sulfur dioxide. Sulfur production was ≤ 150 t/d at 99.99 % purity [98].

In the late 1960s, Foster Wheeler Energy, Livingston, New Jersey, began development of a sulfur dioxide reduction process, using coal as reducing agent. The commercial-size demonstration plant, with a Bergbau-Forschung activated-coal SO_2 concentrator as front end, was erected in 1974 in Lünen, Germany. The process, called Resox (Fig. 51), is based on the direct reduction of sulfur dioxide to sulfur or hydrogen sulfide by passing it, together with steam at 550 – 800 °C (the temperature depends on the type of coal), through a bed of rice-grain-sized coal, contained in a vertical reaction vessel. The coal moves slowly downward, countercurrent to the gas stream. The sulfur is condensed from the gas stream in the sulfur condenser. The gas is then incinerated and returned, partially to the reactor, partially to the SO_2 concentrator [98], [102], [103].

Figure 51. The Resox process

The Sulf-X process, which has been developed and tested in a small-scale plant by Pittsburgh Environmental and Energy Systems, uses for the reduction of sulfur dioxide a complicated conversion via a solution of ferrous sulfide – ferrous sulfate – sodium sulfide – sodium sulfate. Dry, crystalline sodium sulfate is then calcined with coke to give sodium sulfide [104].

In the late 1960s, Outokumpu Oy, Finland, developed a process for conversion of sulfur dioxide in the uptake shaft of copper or nickel flash-smelting furnaces (Fig. 52). After the gas temperature has been increased to 1300 – 1350 °C by combustion of a hydrocarbon fuel, the powdered coal is fed into the shaft; the reduced gases are cooled, cleaned, and catalyzed to convert all sulfur compounds into elemental sulfur, which is condensed by cooling. The sulfur capacity of the pilot plant, operated at the research center at Pori was ca. 5 – 6 t/d. Two industrial-scale plants were built, but neither was put into operation [105].

Figure 52. The Outokumpu reduction process (pilot plant)

a) Dryer; b) Air preheater; c) Fluidizing chamber; d) Flash furnace; e) Waste heat boiler; f) Electrostatic precipitator; g) Sulfur condenser; h) Hot catalyzer; i) Cold catalyzer

In 1983 – 1986, Outokumpu Oy developed a new reduction process, called Sulfred, and tested it as pilot equipment, with a

gas capacity of 2000 – 10 000 m^3/h, installed at the Outokumpu Pori Works. The process (Fig. 53) is characterized by four main steps in two closed chemical cycles. In the first step, sulfur dioxide from the flue gas is absorbed in aqueous sodium sulfide. A small bleed of the washing solution goes to the autoclave stage, where intermediate product, formed in the absorption tower, is decomposed at elevated pressure to liquid sulfur and sulfate. The molten sulfur settles to the bottom of the autoclave, where it is drawn off. The sodium sulfate solution is converted in the regeneration stage to sodium sulfide solution by adding solid barium sulfide, forming insoluble barium sulfate, which is filtered out and reduced back to barium sulfide in a rotary kiln by means of low-ash coal. The process, which has some similarity to the Sulf-X process, has not been commercialized up to now [106].

Figure 53. The Sulfred process

Many patents for different reduction processes exist, but little is known of their testing or commercialization [107-115].

9. Commercial Grades and Forms of Sulfur

9.1. Quality

Frasch sulfur is usually classified in three grades:

1. Superbright: maximum organic content 0.02 % C; guaranteed purity 99.5 %
2. Bright: maximum organic content 0.04 % C
3. Dark: maximum organic content 0.2 % C

There is also Lacq quality sulfur, which is 99.9 % pure (dry basis), and contains 0.01 – 0.03 % organics, 0.01 – 0.05 % ash, and ca. 0.5 % moisture, but no arsenic, fluorine, or bitumen.

As the greatest part of sulfur produced is converted into sulfuric acid, the international standards for this use are of great importance (Table 2).

Table 2. International standards for sulfur in sulfuric acid production

	Liquid	Solid
Purity	> 99.9 %	> 99.7 %
Carbon	< 0.02 %	< 0.05 %
Sulfuric acid	< 0.01	< 0.01
Hydrogen sulfide	< 10 mg/kg	< 10 mg/kg
Moisture		< 2 %
Color	bright yellow	
Commercially free of As, Se, Te, i.e., < 5 mg/kg of each		

9.2. Commercial Forms for Bulk Transport

9.2.1. *Dry Bulk Sulfur*

Until the end of the 1960s, the standard method of sulfur storage was vatting at the production site, the molten sulfur being poured into vast open-air rectangular shuttered frameworks, typically containing 0.25 – 1×10^6 t or even more, and left to solidify. These sulfur stockpiles have played a vital role in balancing supply and demand, being built up during periods of slack demand and drawn on at times when demand has exceeded the rate of production. Solid sulfur is quite brittle and sulfur stored in vats can be reclaimed by mechanical excavators. The larger chunks may have to be crushed, to produce a product consisting of a mixture of particles, ranging from coarse lumps to very fine dust. This material can be handled and transported in much the same fashion as ores and other bulk solids. Apart from the obvious disadvantage that a material of this kind is liable to contamination from moisture, soil, rust, or other impurities during outdoor storage and handling, the dust constitutes a major safety and environmental hazard — the danger of explosion, pollution of the surrounding area by formation of prominent yellow deposits, as well as chemical hazards to the soil and plant life. Because of this, an increasing share of sulfur is now reclaimed from the vat in the molten phase with an in situ remelter; several different systems exist, but in all of them steam is used as the heating medium. Some states have prohibited the movement of dry bulk sulfur, and techniques for remelting vatted sulfur in situ have attracted considerable interest [116], [117].

9.2.2. *Liquid Sulfur*

The majority of the elemental sulfur used in industry goes into the production of sulfuric acid, for which purpose it is needed in the molten state. This is also the state in which it is produced in all the most important primary production

methods, and because of the very low thermal conductivity of sulfur, it can easily be maintained in the liquid state for storage and transport with relatively low amounts of heating. Molten sulfur is easy and quick to load and unload; but the loading and unloading facilities require considerable investment, and they can be used only for this single material, unlike the facilities for handling solid sulfur. The major handling problem is the possible release of gaseous hydrogen sulfide, which is extremely toxic and flammable [118].

Rail is probably the most common transportation method. Liquid sulfur is typically carried in a tank-train system which can be loaded and unloaded through a single connection at rates up to 9000 L/min. This corresponds to a discharge rate for individual tank-wagons of 10 min. In addition, the single connection minimizes possible spillage, and allows single-point collection of hydrogen sulfide vapor.

Trucking is often used to transport sulfur from remote plants to a railhead. Trucks may haul from 22 t on single trailers to 35 t on dual trailers, depending on the terrain and local load restrictions. On privately owned purpose-built roads, payloads up to 87 t may be hauled, as at the Amoco-operated Whitney Canyon plant in Wyoming [119].

Where adequate waterways are available, molten sulfur is generally transported in barges, usually of 2500 t capacity and containing several insulated tanks, which like trucks, tankers, and tank-wagons contain coils heated by steam generated on board. During loading and unloading, the tanks are connected to the loading system by steam-jacketed piping, which provides loading rates up to 1120 t/h. Shipping of molten sulfur began in about 1945, and the proportion of sulfur delivered by barges increased very rapidly. The key routes are in the Mississippi – Missouri river system, and the Rhine.

Seagoing vessels, for liquid sulfur transport are 20 000 – 30 000 t deadweight tankers with isolated tanks and steam coil heating. The rapidly increasing costs of building specialized ships for sulfur transport are the main reason that the seaborne liquid sulfur trade is declining. The fleet is contracting and aging; there were 21 ships in 1992 [120].

Transporting liquid sulfur by heated pipelines within the process plant or refinery has been carried out for many years. There are also a small number of pipelines operating successfully to transport liquid sulfur over long distances, e.g., the 14.5-km undersea pipeline between the Grand Isle sulfur dome in the Gulf of Mexico and the United States mainland, and the 7-km electrically trace-heated line in the north of Germany [121], [122]. There is also a 20-km insulated and electrically trace-heated pipeline from the Berri natural gas plant to the Jubail sulfur terminal in Saudi Arabia [123].

Two main problems have tended to inhibit large-scale transport of sulfur by pipeline: the rather narrow temperature range, 120 – 150 °C, at which liquid sulfur can be transported; and the poor thermal conductivity of solid sulfur, which makes it impossible to remelt the contents of the pipeline should they solidify. A standby heating system, using electricity, steam, or hot water must therefore be available. The viscosity of liquid sulfur is almost ten times that of water, but the power requirement for a liquid sulfur pump need be only 1.8 times that required for pumping water [124].

9.2.3. *Formed Sulfur*

It is not always practical to handle and transport liquid sulfur. For many years the sulfur industry has sought a method of forming sulfur into regularly sized particles which are resistant to attrition and can be handled without the disadvantages associated with dry bulk sulfur.

Processes for forming sulfur have been used since the 1950s, when they were mainly employed in refineries and small-scale units [125]. Flaking — cooling of sulfur on a rotating steel drum — became common after it was developed by Escher Wyss. Slating, installed first by the Swedish-based steel company Sandvik, was used in relatively small-scale units. As sulfur production increased during the early 1960s, flaking became unsuitable, and air prilling, pelletizing (water prilling), and granulating processes were developed in Europe. It was not until the early 1970s, that large-scale sulfur forming facilities became widespread.

9.2.3.1. *Slating*

Slating is one of the most widely used forming techniques in terms of tonnage produced, and is also one of the easiest and least expensive. Molten sulfur is cast onto a continuous conveyor belt and cooled, directly or indirectly, with water so that it solidifies into a thin sheet, usually 3 –20 mm thick. As it reaches the end of the belt, this sheet is broken, or breaks naturally, into smaller pieces that resemble slates.

The first large-scale slating process was installed in 1970 by Vennard & Ellithorpe (now the Sulfur Services Division of Procor, Calgary, Canada) [126]. It uses a two-stage cooling system. From the first stage (tube-and-shell heat exchanger), where the sulfur is cooled to 120 °C, the sulfur is conveyed to the slating unit, which consists of an endless rubber belt with a small retaining ridge at each side. Sulfur solidifies at ca. 113 °C and is cooled to < 50 °C by immersing the belt in water.

Procor now offers a slating unit with two-stage cooling on the slating belt; the initial cooling occurs by aid of hooded fans; in the second stage the belt is submerged in cooling water at 37 °C. The slates are irregular in shape, but have uniform thickness of 5 – 10 mm. The moisture content of the slates is said to be < 1 % [127].

In the Sandvik process, molten sulfur is fed from a steam-heated feeder on the top of a moving endless steel belt, which is cooled by water sprayed against its underside. At the end of the belt, the thin, solid strip of sulfur has cooled to a temperature of ca. 90 °C, and is broken into slates (Fig. 54). As there is no direct contact with the cooling water, the product remains dry and the cooling water can be recycled [128].

Figure 54. The Sandvik slating process

a) Steam-heated weir; b) Conveyor; c) Product breaker; d) Motor

The similar Rotoform process, also developed by Sandvik, uses a patented rotating dropformer, the Rotoformer (Fig. 55), which forms individual lenticular particles or pastilles which are laid on a steel belt, and cooled from the underside, to solidify them. The belt is much shorter than that used in the slating process. The process is economical and reliable, and environmental pollution is negligible [129]. A similar, fully automatic process, the Kaiser Rollomat, is available [130].

9.2.3.2. *Wet Pelletizing (Water Prilling)*

In the Sulpel process, developed by Elliot Associated Developments, London, and now offered by Humprey & Glasgow [131], [132], molten sulfur is dropped through specially designed nozzles into water, maintained in a vortex by swirl jets. The sulfur solidifies into spherical pellets, 0.5 – 6 mm in diameter with a bulk density 1280 – 1400 kg/m^3, which are removed from the bottom of the quench tank, dewatered, and, if necessary, dried (Fig. 56).

Figure 56. The Sulpel process

a) Pelletizer; b) Solution cooler (or air- cooled exchanger); c) Rotary valve; d) Dewatering screen; e) Fines screen; f) pH control (ammonia); g) Solution pump; h) Solution tank; i) Metering pump

In 1975, the Capsul process was introduced by Agra Chemicals, Canada, and Frit Industries, United States [133]. Molten sulfur is fed from a surge tank to the pelleting tank through a vortex chamber nozzle, which produces a diverging conical sheet of sulfur. Pellets from the bottom of the tank are raised by an air lift onto a dewatering screen and dried (Fig. 57). The bulk density of the pellets is 1152 kg/m^3.

Figure 57. The Capsul process

a) Pelleting tank; b) Heat exchanger; c) Dewatering screen; d) Drier (optional); e) Molten sulfur surge tank; f) Settling tank; g) Molten sulfur pump; h) Water tank; i) Water circulating pump

Real International Marketing, Calgary, Canada, offers the RIM process, previously known as the Fletcher process. Sulfur is distributed under gravity through a heated perforated plate distributor into the quench water. The pellets, which are of irregular shape, with a size range of 1 – 10 mm and bulk density 1161 kg/m^3, are then fed to dewatering screens (Fig. 58).

Figure 58. The RIM process

a) Forming unit; b) Cooler; c) Water pump; d) Separator

PV Commodity Systems, Canada, have developed a similar process; sulfur is distributed into quench water with the aid of a perforated plate; a drag-flight conveyor, which removes the pellets, also induces the required movement of the quench water.

Liquid Terminals, Corpus Christi, have developed a process based on the submerged spray technique. The product "nuggets", with a particle size between 10 mm and fines, are markedly less prone to dusting than is slated sulfur. The capacity of a standard commercial unit is 85 t/h [134].

Other slating and pelletizing processes are described in the literature [125], [128], [135], [136].

9.2.3.3. *Air Prilling*

The first air prilling process was developed by Outokumpu Oy, Finland, and was operated between 1962 and 1977. Sulfur is sprayed by the prilling head, located in the prilling tower, together with compressed air and cooling water. The prills are 0.5 – 3 mm diameter, with bulk density 1200 – 1300 kg/m^3.

In the 1960s, a new air-prilling process was developed by Ciech in Poland. The world rights to this technology, known as the Polish air-prilling process, are now owned by Intcan/Technoex, Canada. Liquid sulfur is filtered, and cooled in tube-and-shell heat exchangers to 125 °C. The sulfur is then transported via a feed tank to the top of the prilling tower 65 – 90 m high, 12 – 24 m diameter (Fig. 59). The prills are 1 – 6 mm diameter, with bulk density 1040 – 1200 kg/m^3 [125], [135].

Figure 59. The Polish air-prilling process

a) Aerial condenser; b) Cooler I; c) Cooler II; d) Sulfur filter; e) Sulfur feed tank; f) Sulfur feed pumps (two spares)

9.2.3.4. *Other Prilling Processes*

Union Oil, California, has developed a process in which the product, called popcorn sulfur, is formed by spraying equal amounts of molten sulfur and water through a high-pressure nozzle directly onto a stockpile. The product, small particles, which have to be drained, is used in agriculture.

The Brazilian oil company, Petroleos Brasileiros, developed at its Gabriel Passos refinery an open-air granulation system in which the liquid sulfur is sprayed together with cooling water onto a rotary plate. The sulfur droplets produced solidify rapidly before falling onto a pile below. The water quickly drains from the pile, so that the sulfur moisture level falls to ca. 4 % after ca. 50 h. The investment cost of this simple installation is very low [137].

9.2.3.5. *Drum Granulation: The Procor GX Process*

Procor have developed the GX granulation process, based on the enlargement of "nuclei" or "seed" material in a granulation drum (Fig. 60). Liquid sulfur is sprayed through a series of nozzles to the already solidified particles, falling from the lifting flights of the drum, coating them and increasing their size. The system uses humidified air at ambient temperature as coolant. The drum is 2.4 m diameter, and 10 m long. The seeds, displaced from the drum are 1 – 6 mm diameter [127], [135], [138].

a) Seed feed conveyor; b) Sulfur spray header; c) Cross-flow fans; d) Humidification nozzles; e) Granulation drum; f) Dust preseparator; g) Drum drive; h) Thermocouple; i) Screen

9.2.3.6. *Spouted Bed Granulation*

PEC Engineering, Paris, offers the Perlomatic process, based on the spouted bed principle. Sulfur is sprayed into an upward current of fluidizing air in the throat of a Venturi vessel; it is cooled by the air, and granulates in the chamber above the Venturi cone (Fig. 61). Some of the granules leave the spouting bed with the stream of cooling air; the rest fall down and are removed to screen. The spherical granules produced have a size of 1 – 5 mm, and bulk density ca. 1000 kg/m^3 [139].

9.3. Special Forms and Grades

There are a number of special forms of elemental sulfur, produced for particular agricultural and industrial applications. Their most important characteristic is the fineness of particle size. These special grades are generally referred to as "refined sulfur"; they account for not more than 2 % of total sulfur production.

Ground sulfur is produced by milling to a particle size of 100 – 325 mesh; it is used for protection of some agricultural products, as a fertilizer, and as a vulcanizing agent.

Granulated sulfur is broken sulfur in all grain fractions from 50 mesh to 50 mm.

Micronized sulfur, which is even finer than ground sulfur (< 5 µm), is produced either by milling or via an emulsion of sulfur in superheated water with subsequent rapid cooling; it is used as a pesticide.

Flowers of sulfur is a powdered form produced by sublimation of sulfur. It is used in rubber vulcanization, the pharmaceutical industry, and as a fungicide.

Insoluble sulfur is the µ form of sulfur, insoluble in carbon disulfide. It is produced as the residue after extraction of flowers of sulfur with CS_2, or by fast quenching of molten or vaporized sulfur with subsequent extraction by CS_2 to remove soluble allotropes. It is used in the rubber industry, and for production of high-pressure lubricants.

[Top of Page]

10. Uses

More than 85 % of the total world production of elemental sulfur is converted to sulfuric acid. More than 50 % is used for the production of fertilizers (together with pesticides, insecticides, and fungicides, agriculture consumes more than half of the sulfur produced).

The remaining 35 % of the sulfur converted into sulfuric acid goes into the production of detergents, pharmaceuticals, petroleum catalysts, synthetic resins, titanium pigments, viscose, acetates, and explosives; other uses of sulfuric acid are as a pickling agent in steel production, and leaching of nonferrous ores.

An important nonacid application of sulfur is in the manufacture of carbon disulfide, which can be synthesized either directly from the elements or by the reaction of sulfur with methane, with hydrogen sulfide as byproduct. The principal use of carbon disulfide is the production of cellulose xanthate in the manufacture of products such as viscose rayon or cellophane. Carbon disulfide is also used as a solvent for sulfur, iodine, phosphorus, and rubber.

In the sulfite process for manufacturing wood pulp for the paper industry, sulfur is burned to SO_2, which is then converted to sulfurous acid and subsequently to sulfite, a principal component of the cooking liquor for wood chips. For a variety of reasons, the use of sulfur in pulp making is decreasing [140]. Sulfur dioxide is also used for refining and bleaching in the sugar industry.

Soluble and insoluble sulfur is used as a vulcanizing agent for rubber. Other users of elemental sulfur are the pharmaceutical, cosmetics, photographic, soap, and dye industries.

A survey of sulfur use in the United States in 1989 and 1990 is given in Table 3 [141].

Table 3. Sulfur demand by end use in the United States (kt)

	1989	1990
Food and related products	*	*

10.1. Agriculture

Plant Nutrition. Sulfur is, after nitrogen, phosphorus, and potassium, the fourth major plant nutrient, and is essential for crop growth. Its vital role is to form the amino acids methionine, cystine, and cysteine, which are crucial to the formation of proteins. Sulfur reduces the quantity of nonprotein nitrogen and nitrate; it is also necessary for the formation of chlorophyll, enzymes, and vitamins [142-145].

There is undoubted evidence of sulfur deficiency in soil in some areas of the world [146-148]. A slight deficiency affects crop yield and quality, while the symptoms of severe deficiency are yellowing of the leaves and dwarfing of the plant. The main reasons for the sulfur deficiency are:

1. Increasing levels of specific agricultural production, with proportional increase of sulfur uptake
2. Shift in fertilizer practices, from ammonium sulfate and single superphosphate, to multinutrient (compound) fertilizers with little or no sulfur
3. Decrease in the atmospheric sulfur supply, owing to increasing environmental controls on sulfur dioxide emissions
4. Decline in the usage of sulfur-based herbicides and pesticides

The crop yield in sulfur-deficient areas can be improved by application of sulfur- containing fertilizers. The common dry fertilizers of this type are ammonium sulfate, gypsum, single superphosphate, and potassium sulfate; the liquid fertilizers are ammonium thiosulfate, ammonium bisulfate, and ammonium polysulfate. Sulfur can also be added to some nonsulfur fertilizers (in combination with phosphate rock, sulfur-coated urea, and potassium chloride) [148]. Sulfur – bentonite is a new type of fertilizer, typically 10 % bentonite and 90 % sulfur. The bentonite swells in contact with water and the sulfur particles disintegrate to particles of varying size, which secures the availability of sulfur to the plant over a long time period [149].

Fungicides and Pesticides. Fine elemental sulfur has been used traditionally as a fungicide. Because of the development of highly effective organic fungicides, this use of elemental sulfur is declining. Nevertheless, sulfur, generally applied by spraying, has the advantage of not being consumed by the plant; residues are washed off by rain and act as a nutrient in the soil.

Organic sulfides, sulfones, and sulfonic acid esters are used as long-acting, low-toxic acaricides (anti-mite agents) [150].

10.2. Construction Materials

Sulfur Concrete. Two types of sulfur-containing concrete can be distinguished [151-153]:

1. Hot mixed/hot poured sulfur concrete, in which plasticized sulfur is used instead of portland cement as binder; conventional materials, sand and coarse aggregate, are added
2. Sulfur-impregnated concretes, in which conventional materials such as coarse cement – water – aggregate are impregnated with liquid sulfur, which helps to increase both strength and resistance to corrosion

Sulfur concrete has excellent properties for use in corrosive environments, it sets quickly, can be used in freezing conditions, and is less porous than conventional concrete. The main drawback is its loss of structural strength above 105 °C, as well as its flammability, which excludes it from commercial and residential construction.

The United States Bureau of Mines has developed a modified corrosion-resistant sulfur concrete known as Chempruf [154]. The technology and equipment for its production and pouring is owned by National Chempruf, a United States, British, and Danish consortium, which also markets the product. Chempruf consists of 16 % sulfur cement, 38 % coarse aggregate, 38 % fine aggregate, and 8 % mineral filler. The sulfur cement itself consists of 95 % sulfur and 5 % plasticizer. Chempruf is extremely resistant to most mineral acids and salts and its strength develops very rapidly, to a level higher than that of Portland cement concrete. It has been commercially used for replacement of Portland cement curbs supporting the rails in the cell house of a United States zinc plant. The cost of Chempruf, 2 – 4 times that of Portland cement concrete, limits its use to highly corrosive environments.

Sulfur – Asphalt Compositions. The use of sulfur to modify asphaltic binders, with the aim of improving their properties, has been known for well over 100 years. The addition of sulfur to asphalt compositions increases their resistance to wear and to diesel fuel and gasoline. The viscosity of a sulfur – bitumen mix is lower than that of pure bitumen, which makes its preparation and laying easier. The main concern is the possibility of evolution of hydrogen sulfide during processing of the mix. There are essentially two preparation methods:

1. The sulfur, asphalt, and aggregate are mixed directly together
2. The asphalt binder is first blended with the aggregate, and the sulfur added subsequently

The use of sulfur – asphalt has been studied in many road trials in Canada, United States, United Kingdom, France, and Saudi Arabia [155-159], but no large-scale application of this material is known.

10.3. Sulfur-Containing Batteries

The lithium – sulfur dioxide battery, which has significant advantages over the conventional zinc – carbon battery, is manufactured and marketed in Europe by Vidor, a subsidiary of Crompton Parkinson. However, the cost of electricity generated by this type of battery is ca. 6 – 7 times that of a conventional cell [160].

The sodium – sulfur battery has about four times the storage capacity of a lead – acid accumulator, on a capacity/weight basis, and is seen as a possible energy source for electrical vehicles [161], [162]. Batteries of this type, which operate at ca. 350 °C and require high-purity sulfur, are at present under development by several companies. Because of the small quantity of sulfur per battery (ca. 80 – 90 kg per vehicle), even extensive production of such vehicles would not substantially influence the sulfur market.

10.4. Other Potential Uses

Another potential application of sulfur is the use of sulfur foams in road building in permafrost areas. The foam, with carbon dioxide as blowing agent, is laid as an insulating layer in the foundations of roads to prevent subsidence due to thawing

[163-166]. The foams apparently show very good resistance to freeze/thaw cycles. Foamed sulfur has also been proposed as sheathing for electric cables, on account of its very high resistivity.

Elemental sulfur possesses excellent resistance to attack by a wide variety of acid and salts. Trials have therefore been conducted on the use of plasticized sulfur as a protective coating for conventional concrete surfaces exposed to corrosive conditions around chemical plants, and as a sealant for earth containment dikes around petroleum product storage tanks [163], [167]. Sulfur impregnation of ceramic tiles, to reduce water absorption and increase frost resistance, has also been patented [168].

1. Introduction

Sulfur dioxide is produced industrially in greater quantities than any other single sulfur compound. It is generated as the first stage in the manufacture of virtually all the sulfuric acid used by industry, irrespective of the basic raw material. It may arguably be considered the linchpin of the sulfur sector of the heavy inorganic chemicals industry.

Sulfur dioxide is generated intentionally by combustion of elemental sulfur or by oxidation of sulfides. Since most carbonaceous or hydrocarbon fuels and the ores of many nonferrous metals contain sulfidic sulfur, vast volumes are also produced involuntarily in large fuel-consuming installations, such as power stations, and in nonferrous metal smelters. On account of its chemical and physiological properties, coupled with the scale on which it is produced, waste sulfur dioxide is now considered as one of the gravest chemical threats to the global environment. Progress has been made in controlling atmospheric discharges of sulfur dioxide from the most amenable sources – an aim towards which much of the technological development relating to sulfur dioxide has been directed in the past decade. However, sulfur dioxide pollution, particularly where it crosses national boundaries, continues to be a matter for argument and debate within and between governments and industry.

Sulfur dioxide has been known since ancient times for its bleaching and disinfecting effects [1]. These days it finds widespread use in a rather diverse range of chemical and other industries, including wood pulping and paper production, textile manufacture and food processing, where it serves as reagent, bleaching agent, preservative or solvent. However, the outstanding use of

10.1002/14356007.a25_569

sulfur dioxide – about 98 % of the total amount used by industry – is in the manufacture of sulfuric acid.

2. Properties

Physical Properties. Sulfur dioxide, SO_2, is a colorless, nonflammable, toxic gas with a characteristic pungent smell and acid taste. Its most important physical properties are summarized below [2–8]:

Molecular mass	64.06
Melting point (101.3 kPa)	−75.5 °C
Latent heat of fusion (at *mp*)	115.6 J/g
Dynamic viscosity at 0 °C	368 Pas
Density at − 10 °C	1.46 g/cm^3
Critical density	0.525 g/cm^3
Critical pressure	78.8 bar
Critical temperature	157.5 °C
Boiling point (101.3 kPa)	−10.0 °C
Latent heat of vaporization (at *bp*)	402 J/g
Standard density at 0 °C (101.3 kPa)	2.93 kg/m^3
Density relative to air (0 °C, 101.3 kPa)	2.263
Molar volume (0 °C, 101.3 kPa)	21.9 L/mol
Standard enthalpy of formation	−4636 J/g
Specific heat capacity c_P (101.3 kPa):	
0 °C	586 J kg^{-1} K^{-1}
100 °C	662 J kg^{-1}K^{-1}
300 °C	754 J kg^{-1}K^{-1}
500 °C	816 J kg^{-1}K^{-1}
c_P/c_v (15 °C, 1013 mb)	1.29

Graphical representations of the temperature functions of the various physical properties can be found in [2,6,9]. Interpolation formulas for thermodynamic characteristics such as specific heat are given in [2,5,7,10,11]. The vapor pressure curve of liquid sulfur dioxide as a function of temperature is shown in Figure 1. Figure 1 also shows the dewpoints of gases of varying sulfur dioxide contents at different pressures. These are important in the production of pure sulfur dioxide by condensation (see 7.1).

The solubility of sulfur dioxide in water rises in proportion to the SO_2 partial pressure in good conformity with Henry's law and is increased by lowering the temperature, as represented graphically in Figure 2 [12]. In solution, sulfur dioxide is present mainly as SO_2 molecules, but Raman spectroscopy confirms the presence of minor amounts of the species HSO_3^-, $S_2O_5^{2-}$ and H_2SO_3 [5]. The latter, sulfurous acid (the anhydride of which is sulfur dioxide), exists only in aqueous solution. Aqueous solutions of alkaline compounds will absorb much more sulfur dioxide than pure water because of the formation of hydrogensulfite and sulfite ions [12].

Figure 1. Vaporization curves for sulfur dioxide
Curve for 100 % SO_2 shows relationship of boiling point to equilibrium vapor pressure. Curves for impure SO_2 mixtures show dependence of dewpoint on SO_2 partial pressure

Figure 2. Solubility of sulfur dioxide in water [12]

The solubility of sulfur dioxide in sulfuric acid is of industrial importance. It first decreases with rising sulfuric acid concentration, reaching a minimum at an H_2SO_4 concentration of

ca. 85 %; beyond this concentration it increases again (Fig. 3) [13].

Figure 3. Solubility of sulfur dioxide in sulfuric acid at $p_{(SO_2)} = 101.3$ kPa [13]

Liquid sulfur dioxide is miscible in all proportions with liquid sulfur trioxide. Sulfur dioxide also dissolves readily in most organic liquids (e.g., methanol, ethanol, benzene, acetone, or carbon tetrachloride). With ether, carbon disulfide, chloroform, and glycol it is completely miscible, even at low temperatures [2,5].

Chemical Properties. Sulfur dioxide is very stable; thermal dissociation becomes significant only above 2000 °C. It can be decomposed by shock waves, irradiation with ultraviolet or X-rays, or by electric discharge [2,5].

The reaction of sulfur dioxide with oxygen to form sulfur trioxide is industrially the most significant of all its reactions because of its importance in sulfuric acid production. In the gas phase, it only takes place at elevated temperatures and, for a satisfactory yield of sulfur trioxide, it requires the presence of a catalyst (see → Sulfuric Acid and Sulfur Trioxide). In aqueous solution, sulfur dioxide is oxidized to sulfuric acid at low temperature by air in the presence of activated coke or nitrous gases, or by oxidizing agents such as hydrogen peroxide.

The reduction of sulfur dioxide with hydrogen, carbon or carbon compounds such as methane or carbon monoxide is also of industrial interest [2,5]. These reactions require high temperatures, or catalysts, or both. They result in mixtures of elemental sulfur and hydrogen sulfide. If carbon or a carbon compound is used as reducing agent, carbon- containing species such as carbon dioxide, carbonyl sulfide, and carbon disulfide are formed as well.

Sulfur dioxide reacts with hydrogen sulfide in accordance with the Claus reaction (Eq. 1). This is the basis of the main method by which elemental sulfur is recovered from hydrogen sulfide in industry (see also → Sulfur, Chap. 6.)

$$SO_2 + 2\,H_2S \longrightarrow 3\,S + 2\,H_2O \qquad (1)$$

Sulfur dioxide generally oxidizes metals at elevated temperatures, simultaneously forming metal sulfides and oxides [2,5].

Liquid sulfur dioxide is a relatively efficient solvent with some waterlike properties [2,3]. Polar inorganic compounds are usually insoluble or only sparingly soluble in liquid sulfur dioxide [2], whereas covalent inorganic and organic compounds are often dissolved, mostly forming stable solvates. The fact that aromatic hydrocarbons dissolve more readily than aliphatics in sulfur dioxide is exploited on an industrial scale for the extraction of aromatics from crude oil (Edeleanu process) [5].

3. Raw Materials for Sulfur Dioxide Production

Sulfur dioxide is manufactured industrially from the following raw materials:

1) Elemental sulfur
2) Pyrite
3) Sulfide ores of nonferrous metals
4) Waste sulfuric acid and sulfates
5) Gypsum and anhydrite
6) Hydrogen sulfide-containing waste gases
7) Flue gases from the combustion of sulfureous fossil fuels

Elemental Sulfur. Elemental sulfur is the most important raw material for sulfur dioxide production worldwide. For information on sources of elemental sulfur and production methods, see → Sulfur.

Today, elemental sulfur used for sulfur dioxide production is considered not only as a raw material but also, to an increasing extent, as an energy source. Modern sulfur-burning plants are

normally connected to a turbo – alternator combination for electrical power production; these are known as cogeneration units. Elemental sulfur is the raw material of choice for production of 100 % sulfur dioxide and of industrially significant sulfites, such as calcium hydrogensulfite solution, which is used in cellulose production. Of the 33.5×10^6 t of elemental sulfur produced worldwide in 1981, almost 28×10^6 t were burnt to sulfur dioxide for conversion to sulfuric acid [14]. The proportion of industrial sulfur dioxide production that is based on elemental sulfur varies in different countries. Of the total amount of sulfur-in-all-forms used for producing sulfur dioxide-containing gases for sulfuric acid production, the share of elemental sulfur was ca. 80 % in the United States, about 50 % in Germany, and probably less than 25 % in the former Soviet Union.

Pyrites. Pyrites and other iron sulfide ores still constitute today, in some countries, an important raw material basis for sulfur dioxide production, especially as the primary stage for sulfuric acid manufacture [15]. The most important iron sulfide minerals are pyrite and marcasite, both FeS_2, as well as pyrrhotite or magnetopyrite, the compositions of which correspond approximately to the formula Fe_7S_8. They occur in varying purity as sedimentary rocks in all formations, and as minor constituents in coal deposits. Pyrites are usually slate gray or sometimes greenish in color, depending on the deposit. Other constituents, apart from gangue materials that are present in varying proportions in pyritic ores include sulfides of nonferrous metals, especially of copper, zinc, and lead as well as, to a lesser extent, cobalt, nickel, manganese, bismuth, silver and gold. In some cases, pyrites may also contain arsenic, antimony, tellurium, and thallium as well as fluorides and chlorides.

The production of pyrites, either as crude pyrites or as beneficiated pyrites, has decreased drastically within the last years. This was a result of a depressed fertilizer market, lower sulfur prices, and increasing amounts of involuntarily produced sulfuric acid. Flotation pyrites are, however, obtained in markable quantities as a byproduct of nonferrous metal sulfide beneficiation plants. The sulfur content of pyrites concentrates may be as high as 50 %. Average analyses of pyrite ores of different origins are presented in Table 1.

Depending on the grain size, a distinction is made between flotation pyrites (grain size < 0.1 mm), fine pyrites (0 – 6 mm), coarse pyrites (1 – 12 mm and more), and lump pyrites (10 – 100 mm and above).

Whereas in Japan, for instance, all the pyrite ores produced are processed exclusively in the country, other countries still export pyrites as raw materials for sulfuric acid production, especially the former Soviet Union, Spain, and Norway. In 1982, the Soviet Union exported about

178 000 tonnes S, Spain 145 000 tonnes and Norway 82 000 tonnes S in the form of pyrites [16]. From 1965 until about 1975, world pyrites extraction remained almost constant at an annual rate of about $10-12\times10^6$ t sulfur content. But, as industrial sulfur demand increased substantially during that period, pyrite was in fact declining consistently in its relative importance among the sulfur raw materials. Processing of iron sulfide containing gold and silver ores has increased in importance, resulting in additional involuntarily produced SO_2.

Nonferrous Metal Ores. Nonferrous metal sulfide ores are another important raw material source for sulfur dioxide production. In the pyrometallurgical processing of sulfide ores for extraction of copper, nickel, zinc, and lead waste gases containing sulfur dioxide are inevitably produced. In most countries it is no longer permissible, for environmental reasons, to discharge these gases directly into the atmosphere because of the large plant capacities used nowadays. The development of the various smelting processes is, therefore, strongly influenced by the dual needs to capture the released sulfur dioxide as completely as possible and to generate waste gases with high sulfur dioxide concentrations so that they can be processed as economically as possible [17].

The rate at which sulfur dioxide is produced in the processing of nonferrous metal sulfide ores can be estimated approximately on the basis of metal smelter production statistics, assuming characteristic mean sulfur/metal weight ratios in the ore concentrates of each metal. For 1992 a figure of ca. 20×10^6 t of SO_2 can be given. A comparison of smelter productions for the most important nonferrous metals in 1979 [18], which can be assumed to be based mainly on sulfide ores or concentrates enriched by flotation, is given in [18].

Other Materials. Sulfur dioxide is normally only recovered for environmental reasons from waste sulfuric acid and sulfates, from hydrogen sulfide-containing industrial waste gases and from power station flue gases. Calcium sulfate, in the form of natural gypsum or anhydrite, was formerly used in a few small plants as raw material for sulfur dioxide and sulfuric acid production, but on account of their high energy consumption such plants have either been shut down or modified to process waste gypsum (e.g., from phosphoric acid manufacture).

All sulfur raw materials, except for elemental sulfur and pyrites, are summarized in the statistics under the general item of "sulfur-in-other-forms". The worldwide production of "sulfur-in-other-forms" (with nonferrous metal ores playing the dominant role) amounted in 1982 to about 8.2 million tonnes, of which approximately 7.5 million tonnes were consumed in sulfuric acid production, corresponding to 18 % of the total amount of sulfur used in the production of sulfur dioxide in sulfuric acid manufacture. The most important sources of sulfur-in-other-forms accounted for the following quantities in 1982 (in 10^3 t of sulfur) [16]:

former Soviet Union	1700
United States	1378
Japan	1371
Canada	430
Federal Republic of Germany	408
Finland	221
Australia	160
Italy	152

4. Production from Elemental Sulfur

To burn sulfur in accordance with Equation (2), equimolar quantities of sulfur and oxygen are required

$$S\,(\text{rhomb}) + O_2\,(g) \longrightarrow SO_2\,(g)\quad \Delta H = -297\ \text{kJ/mol} \qquad (2)$$

With air, which contains 20.95 vol % O_2, sulfur dioxide concentrations of ca. 20.5 vol % can in theory be obtained. But in practice, to ensure complete combustion of the sulfur, air is generally supplied in excess, as the problems which might result from unburnt sulfur condensing and solidifying in colder parts of the plant are not worth risking.

As a prerequisite for complete sulfur combustion and for maintaining constant sulfur dioxide concentrations under industrial conditions, it is essential for the sulfur to be finely and evenly dispersed and intimately mixed with the combustion air during burning. The general practice to use liquid sulfur at 140 – 150 °C, at which temperature its viscosity is low enough to enable it to be sprayed through nozzles. The high

surface area of the resulting fine droplets aids rapid evaporation (the normal boiling point of sulfur is ca. 440 °C).

During the combustion process, it is S_2 molecules in the vapor phase that are actually oxidized. Evaporation of liquid sulfur initially produces mainly S_8 molecules, which are only decomposed to S_2 to an appreciable extent above 600 °C [19]. More than 60 % of the heat of reaction (about 9280 kJ/kg S) liberated in the combustion of sulfur to sulfur dioxide is theoretically required for preheating the air and sulfur and for evaporation and decomposition of the sulfur at 600 °C. Therefore, favorable combustion is dependent not only on maximum mass transfer velocity but also, very markedly, on intensive heat transfer in the initial phase.

When solid sulfur is used, the lowest ignition temperature in air under atmospheric pressure is ca. 246 °C. However, sulfur dust clouds may ignite spontaneously at temperatures as low as 190 °C, a phenomenon which has to be borne in mind when handling and storing solid sulfur [20].

Sulfur combustion in industrial oxygen or in oxygen-enriched air is generally uneconomic on account of the high cost of oxygen, and it is not currently used on an industrial scale.

The practicable upper concentration limit for the industrial production of sulfur dioxide gases by burning liquid sulfur with air is at about 18 vol % SO_2. Normally, however, the gases from sulfur combustion furnaces associated with sulfuric acid plants contain 10 – 12 vol % SO_2, corresponding to an O_2/SO_2 ratio of ca. 1:1, as required in double absorption plants (see → Sulfuric Acid, Chap. 4.1.4.1.).

Normally the combustion air used in the industrial production of sulfuric acid plant feed gases from elemental sulfur is dried with concentrated sulfuric acid. It is then compressed by a blower to1.3 – 1.5 bar to provide the driving force needed to overcome pressure drop within the rest of the plant. Drying and compression raise the temperature of the air to about 60 – 100 °C.

Theoretically, the combustion temperature is ca. 1000 °C when liquid sulfur is burnt at an initial temperature of 140 °C in dried air originally at 60 – 80 °C to produce a gas containing 10 vol % SO_2. As can be seen from Figure 4, the combustion temperature rises in direct linear proportion to the sulfur dioxide concentration. It reaches about 1600 °C when the combustion gas sulfur dioxide concentration is 18 vol %.

Figure 4. Theoretical sulfur combustion temperature as a function of combustion gas SO_2 concentration (air temperature = 80 °C, sulfur temperature = 140 °C)

4.1. Sulfur Burning Processes

In industry nowadays sulfur combustion furnaces with atomizing burners for liquid sulfur are used almost exclusively. Figure 5 shows the layout of a Lurgi sulfur combustion furnace. The furnace comprises a cylindrical steel shell lined with several layers of insulating and refractory bricks. It is normally arranged horizontally, but when space is limited a vertical version is available. The sulfur burner is mounted at one end of the combustion chamber and a waste heat boiler is connected directly to the gas outlet at the opposite end. The specific furnace size is very much dependent on the type and efficiency of the burner used.

Figure 5. Lurgi sulfur furnace
a) Rotary atomizer; b) Sulfur furnace

Burner Types. There are various ways in which liquid sulfur can be atomized to produce the fine spray needed for the most efficient possible combustion. The main commercial burner types are the pressure-nozzle burner, in which sulfur is injected under pressure through a spray nozzle into the furnace chamber; the two- component burner, in which the sulfur is released through a nozzle into a turbulent jet of air; and the rotary burner, in which the sulfur is distributed centrifugally from the edge of a spinning cup into a stream of air [21, 22].

With the simple *pressure-nozzle burner*, the liquid sulfur is atomized with a single spray head. The relatively high pressure of 8 – 15 bar needed to drive this type of burner is produced by a sulfur pump of special design [23]. A steam-heated double shell around the nozzle pipe serves the purpose of keeping the sulfur molten when the burner is not operating and preventing overheating when it is. The main disadvantage of this type of atomizer is its relatively low flexibility: major changes in the throughput can only be accommodated by changing the nozzle. The smaller-diameter nozzles are also prone to clogging.

The maximum sulfur throughput of a pressure-nozzle burner is ca. 72 t/d. In the relatively large plants commonly used nowadays, it is, therefore, necessary to install several nozzle systems with separate measuring and control instruments. This also increases the flexibility of the system.

Two-component burners, in which the sulfur is chiefly atomized by the combustion air, can be used for extremely low sulfur throughputs of < 7 t/d, for which pressure-nozzle burners are inherently unsuitable. The combustion air flows at high velocity from an annular space surrounding the sulfur nozzle. The sulfur, supplied to the nozzle through steam-jacketed pipes, is entrained in the air stream and finely distributed by turbulence in the combustion air induced by deflector plates. The necessary sulfur pressure is only ca. 2 bar. Modern two- component burners are designed for sulfur throughputs of up to ca. 170 t/d. The turn-down limit is usually around 15 % of capacity, although a compact design intended for small-scale applications such as pulp mills is reported to be able to run at as little as 5 % of its nominal capacity of 5 t/d. This is because a variable-speed sulfur pump is used instead of the more normal check valve arrangement to control the flow of sulfur [24].

The *rotary burner*, represented by the Lurgi-developed Luro Burner, is nowadays the preferred type for large plants. The design of such a burner is shown schematically in Figure 6. The sulfur passes at virtually atmospheric pressure into an open cup rotating at 4000 – 6000 rpm. The sulfur film on the inner wall is dispersed from the edge by centrifugal force and is further atomized by entrainment in the so- called primary air, which emerges at high velocity through the narrow annular space between the rotating cup and the atomizer hood. "Secondary air," constituting the majority of the combustion air, enters the furnace through an annular space between the atomizer hood and the burner casing. A system of adjustable air guide vanes in this space imparts a tangential component to the flow of secondary air as it enters the conical combustion space between the burner and the main furnace chamber. The resulting spiral path of the gases through the furnace not only effectively keeps the flame central but at the same time prevents unvaporized sulfur droplets from impinging on the furnace wall.

Figure 6. LURO rotary sulfur burner
a) Sulfur distributor; b) Atomizing cup; c) Atomizer hood; d) Burner housing; e) Seal air; f) Burner shaft; g) Electric motor; h) Belt transmission; i) Sulfur inlet

A highly advantageous characteristic of rotary burners is that the throughput can be varied continuously from the rated capacity down to 20 % capacity or less without appreciable change in atomizing intensity. Rotary burners can be designed for sulfur throughputs ranging from 5 to 400 t/d. The highly turbulent atom-

izing effect ensures swift and safe combustion of the sulfur, which makes it possible to design for extremely high specific furnace loads (ca. 4 – 8×10^6 kJ m^{-3} h^{-1}) and small specific furnace volumes.

4.2. Heat Recovery

The heat released in the combustion furnace is utilized in a waste heat boiler immediately downstream, generally producing high-pressure steam. In the case of a sulfuric acid plant, gases of 10 – 12 vol % SO_2 leave the furnace at ca. 1100 °C and are cooled to the converter inlet temperature of ca. 420 – 440 °C. The waste heat boiler is coupled with the waste heat system of the contact plant and, in conventional double-absorption contact plants, it accounts for ca. 58 – 60 % of the total energy recovered as high-pressure steam. On the whole, ca. 3.8 – 4.0 t of steam at 40 bar and 400 °C can be produced per tonne of liquid sulfur. If the sulfur is supplied in solid form, about 0.5 t of saturated steam at 5 bar is required per tonne of sulfur for melting, heating the sulfur filters, and tracing the sulfur piping.

4.3. Impurities and their Removal

The 10 – 12 vol % SO_2 combustion gases produced in a sulfuric acid plant contain minor amounts of sulfur trioxide (3 – 6 g/m^3) [25] and up to 20 ppm nitrogen oxides. Other impurities mainly depend on the quality of the sulfur used.

Much of the Frasch and recovered sulfur commercially available nowadays, which is supplied in Western Europe and in the United States mainly in liquid form, is adequate for direct burning without requiring additional cleaning, but various impurities do occur in sulfur, particularly where it is handled and transported in solid form.

Bitumen and hydrocarbons, which occur especially in the so-called dark sulfur grades, burn to carbon dioxide and water. The correspondingly higher moisture content of the sulfur dioxide-containing contact gases can lead to sulfuric acid mists, which are difficult to absorb. In sulfuric acid plants running on dark sulfur, additional equipment, such as candle filters downstream of the sulfur trioxide absorbers, may be necessary to avoid corrosion and emission problems.

Any *ash* in the sulfur may lead to deposits in the combustion furnace and waste heat boiler. However, the major part is entrained as fine dust in the sulfur dioxide-containing gases and passes into subsequent parts of the plant. In a sulfuric acid plant, it is mostly caught in the first catalyst bed. This leads to a progressive increase in the gas pressure drop and may also cause a loss in the sulfur dioxide conversion efficiency. Regular screening of the catalyst may be necessary. Hot gas filters were formerly placed in the gas line upstream of the converter to separate the dust. But they are hardly used any more because they add to the pressure drop and are only partially effective. Sedimentation tanks or settling pits cannot be relied on alone to remove all the solid components from the molten sulfur.

Filtration of the liquid sulfur [26] is the most effective means of separating higher ash contents, which may occur especially in solid sulfur. The sulfur is melted and heated by using low-pressure steam of about 5 bar to a temperature of ca. 140 – 150 °C, at which its viscosity is at a minimum. It is then pumped through vertical or horizontal filters of up to ca. 150 m^2 filtering area. Normally, these are of the pressure leaf type, comprising a battery of stainless steel wire gauze elements suspended in a containing vessel. Each element consists of two fine-mesh filter gauzes suspended in a ring frame and supported and held apart by a third, coarse mesh layer. The intermediate space between the two fine gauzes of each element is connected to the outlet of the filter. In operation, the outside of the filter elements is first coated with a filter aid such as kieselguhr by passing it as a suspension into the filter vessel and recirculating the effluent from the outlet back into the filter feed tank or settling pit. Once prepared in this way, the filter is ready for service. Periodically, as it becomes clogged with ash-forming material from the sulfur, the filter is cleaned and recoated.

Apart from the additional operations and equipment required, sulfur filtration poses a problem to the sulfur user of what to do with the filter cake, which contains ca. 70 % sulfur. As a result, the responsibility for sulfur filtration is increasingly being shifted to the sulfur producer.

4.4. Two-Stage Sulfur Combustion

For producing gases of high sulfur dioxide concentration and extremely low nitrogen oxides (NO_x) content, Lurgi has developed a double-stage process with substoichiometric sulfur combustion [27]. As explained earlier, the combustion temperature increases in proportion to the sulfur dioxide concentration of the combustion gas (see Fig. 4). Above the usual combustion temperature of 1000 °C, formation of nitrogen oxides increases in proportion to the temperature, even though the free oxygen content remaining in the gas is lower when the sulfur dioxide content is higher if the combustion air is not enriched. Only above a concentration of ca. 18 vol % SO_2 is the free oxygen content low enough for thermal NO_x formation to decline drastically. Nitrogen oxides formation is also the factor limiting the extent to which it is possible to preheat the combustion air in ordinary sulfur burning systems, as this raises the combustion temperature.

Nevertheless, formation of nitrogen oxides can be avoided, even at a combustion temperature of 1750 °C, if the combustion of sulfur is divided into two stages. In the first, the sulfur is burnt with a stoichiometric deficiency of oxygen. It is particularly important in that stage to ensure that the gases are extremely well mixed so that all the oxygen is consumed, and nitrogen oxides cannot form. The combustion gas, containing ca. 20 vol % SO_2 and some unconverted sulfur vapor, is cooled in a waste heat boiler to ca. 620 – 650 °C and then passed into the second stage, an afterburning chamber (see Figure 7). There, enough dried air is added to convert the remaining sulfur vapor completely to sulfur dioxide, leading to a final gas concentration of ca. 18 vol % SO_2. On account of the low concentration of sulfur vapor in the second stage, the combustion temperature is too low for nitrogen oxides to form. The gas mixture leaves the afterburning chamber at a temperature not exceeding 700 °C and is cooled in another waste heat boiler (usually designed as a steam superheater) before being passed on to, for example, a sulfur dioxide liquefying or a bisulfite plant. This type of system has been proved in years of satisfactory service in large-scale plants.

The concentration of nitrogen oxides observed in the gases containing 18 vol % SO_2 produced in this double-stage sulfur burning system are actually lower than those of the 10 % SO_2 gases originating from single-stage sulfur burning plants.

5. Production by Pyrite Roasting

5.1. Importance of Impurities

In the production of sulfur dioxide-containing gases by roasting of pyrites, the constituents occurring besides sulfur and iron in the flotation concentrates or fines exert a substantial influence on the selection of the roasting process to be applied and its economics. Pyrite contains ca. 30 – 50 % sulfur, 26 – 46 % iron and up to 2.7 % copper, 3 % zinc, 1.4 % lead, up to 10 % arsenic, and a number of other metals in small quantities (see Table 1). Some of these impurities are entrained with the sulfur dioxide in the roaster gases, and to remove them efficient gas cleaning is necessary.

Impurities are also of prime concern in disposal or utilization of the iron oxide residue of pyrite roasting, the so-called cinder. Each tonne of pyrite concentrate yields about 0.7 t of cinder. High purity is a prerequisite where the cinder is to be used for steelmaking. Cinders within the following specification are generally considered acceptable [28]: Fe 65 %, Cu 0.1 %, Zn 0.1 %, Pb 0.02 %, As 0.06 %, S 0.5 %.

If a pyrite concentrate contains arsenic in larger quantities, special roasting methods have to be used so as to obtain sufficiently low residual arsenic values in the cinder (see Section 5.4).

Nonferrous metals such as Cu and Zn, which are still present in flotation pyrites, are again found in the cinder. At high nonferrous metal

contents, the cinder can be treated by chlorination and leaching.

5.2. Thermodynamics and Kinetics

Four main reaction steps (Eqs. 3 – 6) make up the overall pyrite roasting reaction (represented by Eq. 7). The specified enthalpy values [7] refer to 298 K:

$$2\,FeS_2 \longrightarrow 2\,FeS + S_2(g) \quad \Delta H = +\,293\ \text{kJ/mol} \tag{3}$$

$$S_2(g) + 2\,O_2 \longrightarrow 2\,SO_2 \quad \Delta H = -723\ \text{kJ/mol} \tag{4}$$

$$2\,FeS + 3\,O_2 \longrightarrow 2\,FeO + 2\,SO_2 \quad \Delta H = -\,948\ \text{kJ/mol} \tag{5}$$

$$2\,FeO + 0.5\,O_2 \longrightarrow Fe_2O_3 \quad \Delta H = -\,282\ \text{kJ/mol} \tag{6}$$

$$2\,FeS_2 + 5.5\,O_2 \longrightarrow Fe_2O_3 + 4\,SO_2 \quad \Delta H = -\,1660\ \text{kJ/mol} \tag{7}$$

The endothermic decomposition of pyrites gives FeS or magnetopyrite, liberating sulfur vapor (Eq. 3). If oxygen is available in adequate quantities, the sulfur is immediately oxidized to sulfur dioxide (Eq. 4) and simultaneously the sulfur content of the FeS is converted to sulfur dioxide as well, in accordance with the equally exothermic reaction (Eq. 5). At the temperatures prevailing in the roasting process, the iron(II) oxide (FeO) formed as an intermediate phase is oxidized to magnetite (Fe_3O_4) or hematite (Fe_2O_3), depending on the oxygen ratio (Eq. 6). The overall pyrite roasting reaction (Eq. 7) is strongly exothermic, yielding ca. 13 000 kJ/kg pyrite sulfur. (The corresponding energy yield of burning elemental sulfur is only ca. 9300 kJ/kg of sulfur). The roasting rate depends on the temperature, grain size, and mineralogical composition of the pyrites as well as the oxygen partial pressure.

Iron(II) oxide and sulfide form an eutectic mixture containing 56.2 % FeS and 43.8 % FeO, which melts at 940 °C. It is not possible to increase the reaction velocity by raising the temperature above this value because any molten material deposits on the surface of the pyrite particles. This renders unreacted material inaccessible to oxygen and thus inhibits further reaction, particularly with larger particles.

The ignition temperature of pyrite lies between 350 °C and 550 °C. The finer the grain size and the higher the nonferrous metal content are, the nearer the ignition temperature is to the lower limit. A temperature of at least 800 °C is required for complete reaction; the optimum range is 850 °C to 940 °C, depending on the grain size. A few pyrites decrepitate during roasting. The fine particles thus formed influence the roasting velocity and increase dust formation.

The residual sulfur content of the cinder depends not only on the amount of sulfide remaining unconverted but also on sulfate sulfur. The latter forms chiefly when the pyrite contains nonferrous metal impurities such as copper, zinc, lead, cadmium, magnesium, and calcium, which remain in the cinder as sulfates.

The maximum attainable sulfur dioxide content of the roaster gas depends on the pyrite composition as well as the atmosphere in which it is burnt. In air it is ca. 16 vol % in the most favorable case, although with the slight excess of air usually used values of 13 – 14 vol % are common. In oxygen or oxygen-enriched air, higher sulfur dioxide concentrations can be attained. In spite of the thermal and process advantages that this would have with respect to sulfur dioxide and sulfuric acid production, oxygen is rarely used for pyrite roasting because of the high costs.

5.3. Roasting Processes

Various types of roasting equipment have been used in the past for pyrite roasting, including shaft furnaces, multiple hearth roasters, rotary kilns, and dust roasters [29, 30]. Nowadays fluid-bed roasters are preferred, as they are much superior to the other types in terms of process technology, throughput rates, and economy. As a further step, circulating fluid bed technology was introduced for roasting special ores that containing economically viable quantities of gold.

Basically a fluid-bed roaster is in the form of two upright cylinders, the upper being of a larger diameter than the lower, to which it is joined by a frustoconical section. The steel shell is lined with insulating and refractory bricks. At the lower end is a horizontal bar grate or a nozzle grate, below which is a conical wind box, at the apex of which the roasting air is introduced. In this way the roasting air is uniformly distributed over the entire cross section of the lower portion of the roaster. Above the grate, a bed of cinder

is maintained in a fluidized state by the roasting air. The pyrite is fed into the roaster directly above or in the uppermost zone of the fluid bed. The depth of the fluid bed is kept constant by an overflow. In the wider upper section of the roaster, the velocity of the gas leaving the fluid bed is reduced. This serves to stabilize the top zone of the fluid bed and reduces entrainment of solids in the gas flow. This section also acts as an afterburning chamber. The roaster gases pass from the top of the roaster to a waste heat boiler directly downstream.

Fluid-bed technology for pyrite roasting was first introduced at the beginning of the 1950s almost simultaneously by Dorr Oliver in the United States and BASF in the Federal Republic of Germany.

Dorr Oliver FluoSolids Reactor. In its original concept, the FluoSolids reactor was designed on the wet feeding principle [31,32]. Finely ground ore or flotation pyrites are mixed with water to form a viscous pyrite sludge with a 70 – 80 % solids content. This is forced continuously into the roaster by means of a pump. The height of the cinder bed is up to 1 m in the unfluidized state and 1.6 m when fluidized at a gas velocity in the bed of 0.2 – 0.6 m/s. The specific daily throughput is around 4 – 5 t/m^2 of roaster area. The bed temperature is adjusted to 600 – 900 °C by adiabatic evaporation of the water introduced with the pyrite and (where appropriate) of additional water injected separately. A later version of the FluoSolids roaster was designed for dry feeding, using indirect cooling and heat recovery [33].

The BASF – Lurgi fluid bed furnace roaster was developed [34–36] for dry pyrite feeding and designed to recover the maximum amount of heat for steam production. In this roaster the temperature of the fluid bed is kept constant by indirect cooling; the surplus heat of reaction is removed in the fluid bed by immersed cooling elements which form part of a waste heat system for the production of high-pressure steam. Figure 8 shows a typical design of a modern fluid bed furnace with waste heat system according to the Lurgi principle.

The grain size of the pyrites to be processed may be up to 10 mm, depending on the stability of the particle structure during the roasting process. Usually the particles have diameters of up to 6 mm. The coarser the grain is, the higher the gas velocity must be to maintain the bed in a fluidized state. Even flotation pyrites with grain sizes < 0.2 mm can be processed in the fluid bed roaster, but in that case the moisture content is important. Although the pyrites must be dry enough to be fed in the solid state, enough moisture must be present to ensure that the particles are sufficiently agglomerated to maintain a stable fluid bed. Otherwise the particles will be too light and will be largely blown out of the reaction in the gas flow.

Figure 8. Fluid bed roaster with waste heat system
a) Fluid bed furnace; b) Waste heat boiler; c) Pre-evaporator; d) Superheater; e) Evaporator; f) Steam drum

To ensure uniform, controlled feeding of the pyrites, table feeders or weight- controlled variable-speed conveyors are used. The gas velocity in the fluid bed is ca. 0.8 – 2.5 m/s at 1 bar and 850 °C. In the top part of the roaster the velocity is ca. 0.5 – 1.8 m/s. In the unfluidized state, the bed has a rest depth of 700 – 800 mm.

In contrast with all the earlier roasting systems, the material distribution in a fluid bed system is very rapid, and both the composition of the bed and its temperature are very uniform. Therefore, it is possible to select and maintain the roasting process conditions within a narrow optimum range. On account of the good heat transfer characteristics (800 –1200 kJ m^{-2} h^{-1} K^{-1}) the temperature can be controlled satisfactorily by indirect cooling using immersed, water- cooled elements with a relatively small heat exchange surface area.

The bed temperature is normally maintained in the range 650 – 900 °C. In the gas space above the fluid bed, the temperature may be some-

what higher (up to 950 °C) on account of the afterburning effect when flotation pyrites are being processed. Above the fluid bed the pressure is kept slightly below atmospheric pressure to avoid leakage of sulfur dioxide to the outside. The roaster gases are drawn off from the furnace by the main gas fan of the subsequent contact plant or by an intermediate gas fan in the gas cleaning system.

Abrasion under the turbulent bed conditions and decrepitation of the pyrite particles create a substantial amount of fines, so that a sizeable amount of the solids leave the bed in the roaster gas in the form of dust. This dust is precipitated in the waste heat boiler and also in subsequent cyclones and hot gas electrostatic precipitators. When fine pyrites are roasted, the portion of cinder leaving the roaster as entrained dust may be around 50 % and in the case of flotation pyrite roasting it may even be as high as 90 % or more.

Being predominantly iron oxide, the dust has catalytic activity for the oxidation of sulfur dioxide to sulfur trioxide. This reaction is highly undesirable at this stage because any sulfur trioxide formed reacts with moisture in the gas to form sulfuric acid, which condenses in cool parts of the plant and causes corrosion. In the roaster itself the oxidation of sulfur dioxide is inhibited by the high prevailing temperature and by controlling the air supply to minimize the residual oxygen content in the roaster gas. Having a low oxygen content is of even greater importance in the waste heat boiler, where the gas is cooled to temperatures at which sulfur trioxide formation is thermodynamically more favored. It is also of importance to cool the gases here as quickly as possible to temperatures at which the reaction is kinetically inhibited. Nevertheless, some sulfur trioxide is inevitably formed, and since neither the pyrites nor the roasting air are dried, the roaster gas temperature at the outlet of the hot gas electrostatic precipitator must be maintained above the dewpoint of sulfuric acid. This limits the amount of heat that can be recovered from the gases in the waste heat boiler. Generally, the roaster gases are cooled to about 350 °C before they enter the dust separation cyclone.

Figure 9 shows a typical energy flow diagram for the roasting of flotation pyrites containing 47 – 48 % sulfur in a Lurgi fluid bed roaster system. Approximately 70 % of the total energy is recovered from the fluid bed and roaster gas in the form of high-pressure steam. This corresponds to the production of about 1.5 t of steam of 40 bar and 400 °C per tonne of 48 % S pyrite from feed water at a temperature of about 104 °C. The remaining 30 % of the total energy is represented by the heat content of the roaster gases at an exit temperature of 350 °C, the heat content of the cinder, and radiation losses. The power consumption amounts to a 25 – 30 kWh/t pyrites. Most of it is used in the roasting air fan. The sulfide sulfur content of the cinder from pyrites originally containing 47 – 48 % sulfur is about 0.5 %. The sulfur dioxide content of the roaster gases at the furnace outlet is ca. 14 – 14.5 vol %. The use of an automatic control system to maintain the oxygen content of the roaster gas at the furnace outlet at a minimum substantially reduces sulfur trioxide formation in the waste heat boiler and with it the rate of scrubber acid accumulation in the wet gas cleaning system.

Figure 9. Energy flow diagram for fluid bed pyrite roasting

The specific capacity of Lurgi fluid bed roasters corresponds to a daily throughput of about 20 t/m^2 of roaster area. Today, fluid bed roasters are designed for pyrites throughputs of up to about 1000 t/d. Their turndown limit is around 70 – 80 %. For large plant capacities, in most cases two furnaces are connected in parallel to provide better flexibility.

During start-up, the fluid bed made up of cinder is preheated with oil burners. As soon as the bed temperature reaches ca. 600 °C, pyrites can be fed in and the oil burners are turned off.

On account of the high thermal capacity of the cinder bed, the roaster can be restarted with-

out requiring additional heating after standstills of up to about 24 h.

Circulating Fluid Bed Roasting [37]. A further step towards more efficient roasting – especially of gold-containing ores – was the introduction of the circulating fluid bed process.

The circulating fluid bed (CFB) technology is known from the calcination of hydrated alumina or clay and combustion of coal, and was adapted for roasting of gold-bearing minerals. After extensive pilot plant tests the first industrial scale plant was built by Lurgi and started up in 1989 in Australia.

The aim of roasting gold-containing minerals is to obtain a maximum gold recovery from the calcine in subsequent leaching steps. Such conditions can only be achieved within a narrow range of roasting temperatures and oxygen partial pressures in the roaster gas atmosphere. The CFB process is capable of providing such conditions.

Contrary to a "normal" stationary fluid bed, circulating fluid bed roasters are operated at higher gas velocities in the range of 3 – 6 m/s. Because of the velocity the fine solids (calcine) are entrained with the gas and in part recycled to the roaster via a cyclone.

The main features of the CFB process are:

1) Treatment of a wide range of minerals
2) High heat and mass transfer rates
3) Uniform temperature profile over the whole roaster/cyclone system
4) Accurate temperature control by cooling surfaces, direct water injection, or direct fuel injection
5) Stable oxygen partial pressure all over the system
6) Turndown ratio of 50 %

Ores with sufficient sulfur and iron content can be roasted autothermally; ores with low sulfur and iron contents can be treated with additional heating; and even the most sensitive refractory gold ores can be roasted successfully in the CFB. Air or oxygen-enriched air can be employed. The high heat and mass transfer rates guarantee almost complete combustion of sulfur and carbon. The uniformity of the temperature profile avoids the partial overheating of particles known from stationary fluid beds. Overheating of particles may cause substantial drop in gold recovery. The temperature is uniform in the whole system due to the high amount of circulated material and the effect of cooling (or heating) is transferred to the total inventory of the system. Because of the high velocities and mass transfer rates an exact and stable control of the oxygen partial pressure is possible to obtain optimum roasting results. A turndown ratio of up to 50 % offers a high operational flexibility compared to normal fluid bed roasting.

Key components of CFB plants are the roaster and the recycling cyclone. The roaster consists of a cylindrical shell with insulating and refractory bricks. At the lower end a nozzle grate is installed through which the roasting air is introduced. At the upper end the recycling cyclone is connected to the roaster. The ore is fed to the CFB roaster and roasted with air or oxygen-enriched air. A portion of the hot calcine which is separated in the cyclone is recycled to the roaster, a second portion is transferred to a fluid bed cooler where part of the heat contained in the calcine is removed. The hot gas leaving the cyclone is cooled and treated in downstream plant elements.

The associated equipment must be selected according to the specific requirements of each plant; some of such elements are listed below:

1) Dry feed or slurry feed
2) Preheating and drying of feed with recovered heat from the calcine
3) Preheating of roasting air with recovered heat from the calcine
4) Direct injection of additional fuel (if required)
5) Cooling of the reaction material by integrated cooling elements, direct water injection or recirculation of cooled calcine
6) Cooling of the calcine in a fluid bed cooler, or direct quenching
7) Heat recovery from roaster gas in a waste heat boiler or gas – gas heat exchangers
8) Further treatment of the off-gas (bag house, electrostatic precipitator, acid plant, . . .)

A flowsheet showing the key equipment and some alternatives for associated equipment is given in Figure 10 (see next page).

Roasting in a Cyclone Furnace. Pilot-plant trials have been carried out in Poland on a

Figure 10. CFB-roasting of gold-bearing ores
EP = electrostatic precipitator

method of roasting pyrites in a cyclone furnace, which is claimed to facilitate the subsequent recovery of nonferrous metals [38]. Flotation pyrites, preheated air, and (as necessary) fuel are introduced into the upper section of a cyclone. The operating temperature is such that the burnt particles of pyrite cinder melt, coalesce, and run down the walls of the cyclone. The melt is drained into a quench bath, where it forms granules. The gas leaving the cyclone contains entrained iron oxide droplets and part of the original nonferrous metals content of the pyrites, especially zinc and lead, both as particles and vapors of oxides and metals. It is cooled in a fluid bed cooler with immersed cooling coils, which recover the heat partly as high-pressure steam and partly by preheating the furnace air. The entrained material and vapors of nonferrous metals are largely arrested by agglomeration in the fluid bed. The material overflowing from this bed is stated to contain a substantially higher concentration of nonferrous metal values than the cinder from other types of roasting furnace.

5.4. Roasting of Arsenical Pyrite

Arsenic occurs in pyrites in the form of arsenical pyrite (FeAsS; $FeAs_2 \cdot FeS_2$). Under the usual roasting conditions, with a slight excess of oxygen in relation to the stoichiometric requirement for converting the iron content of the pyrite to hematite, the majority of the arsenic is oxidized to As(V) and will react with the hematite to form stable iron arsenate ($FeAsO_4$). In this way about 70 – 80 % of the arsenic content in the pyrite feed becomes bound to the cinder. The remaining arsenic, which is oxidized to As(III) as shown in Equation (8), is volatilized and entrained by the roaster gas and must be separated in the wet gas cleaning system

$$2\,FeAsS + 5\,O_2 \longrightarrow Fe_2O_3 + 2\,SO_2 + As_2O_3 \qquad (8)$$

If the cinder is to be used in steelmaking, itmust not contain too much arsenic. In such cases high-arsenic pyrites can be processed in a two-stage

fluid-bed roasting system. In the first stage, operating under oxygen-deficient conditions, neither hematite nor iron arsenate is formed. The arsenic is thus volatilized almost completely and discharged with the roaster gases. In the second fluid bed stage, the separated cinder is oxidized to hematite. This principle is applied on an industrial scale in the Boliden roasting process and the BASF two-stage process.

Both the Boliden and BASF processes are capable of diminishing the residual arsenic content of the cinder to less than 0.05 %.

Boliden Process. The Boliden process [28] was specifically developed for processing arsenical flotation pyrites. In the fluid bed roaster, the roasting air/pyrites ratio is adjusted so that magnetite forms at ca. 850 °C. Most of this is blown out of the furnace in the roaster gas. It is separated at an efficiency of ca. 90 % in a hot-gas cyclone immediately following the furnace. The gas leaving the system contains, besides residual dust, the arsenic and ca. 10 g/m^3 of sulfur vapor. The sulfur vapor is burnt in a special combustion chamber at the inlet of the waste heat boiler with a controlled amount of additional air. More air is added at the waste heat boiler outlet to complete the combustion of residual traces of sulfur before the gases pass on to the hot gas electrostatic precipitator. The cinder separated from the gas in the hot gas cyclone is treated in a second fluid bed roaster with a controlled volume of air. In the process, the residual sulfur level is diminished substantially, and the magnetite is partly converted to hematite (Eq. 9)

$$2\,Fe_3O_4 + 0.5\,O_2 \longrightarrow 3\,Fe_2O_3 \quad \Delta H = -57.3\,\text{kJ/mol} \qquad (9)$$

As in the first roaster, the surplus heat of reaction is recovered by generating steam in cooling coils immersed in the fluid bed. The discharged cinder is cooled to ca. 200 °C in a separate fluid bed cooler, which is connected into the steam system as a preheater. Up to ca. 1.6 t of high-pressure steam at approximately 425 °C are produced per tonne of pyrites.

The arsenic is removed from the dedusted roaster gases in the wet gas cleaning system (see Section 6.2). Plants built under license by Lurgi processing up to 500 t/d pyrites have been operated successfully in Sweden, Spain, and Japan.

BASF Process. The BASF two-stage process [39] is especially suited for processing relatively coarse pyrites. Partial roasting in a first fluid bed unit at 900 °C under oxygen-deficient conditions removes only the loosely bound polysulfide sulfur of the pyrite, giving FeS.

$$FeS_2 + O_2 \longrightarrow FeS + SO_2 \quad \Delta H = -215\,\text{kJ/mol} \qquad (10)$$

Arsenic, antimony, and lead are carried out of the system with the roaster gases, mainly as volatile sulfides or oxides. Coarse ferrous sulfide cinder withdrawn directly from the bed overflow and hot dust separated in the high-efficiency cyclone are passed on to a second fluid bed unit. The iron(II) sulfide, which is virtually free from arsenic, is roasted at about 800 °C with excess oxygen to obtain hematite.

The roaster gas from the first stage leaves the hot gas cyclone with about 18 vol % SO_2. It is first passed with additional air through an afterburning chamber to oxidize any remaining sulfur vapors and residual sulfides. The gases are then cooled in the waste heat boiler. The dust separated there and in the hot gas electrostatic precipitator immediately downstream is rich in arsenic, antimony, and lead and can be treated further to recover them. But the main part of the arsenic remains in the gases as volatile arsenic trioxide and is separated in the wet gas cleaning system.

The gases originating from the second roaster stage, with about 10 vol % SO_2, are cooled in another waste heat boiler and dedusted in a cyclone followed by a hot gas electrostatic precipitator. The gas streams from the two stages are subsequently united (upstream or downstream of the wet gas cleaning system).

In the low-arsenic cinder and dust coming from the second stage, the iron is present as hematite (Fe_2O_3).

5.5. Production in Nonferrous Metal Sulfide Ore Processing

5.5.1. Copper Smelting (→ Copper, Chap. 5.3., → Copper, Chap. 5.4., → Copper, Chap. 5.5., → Copper, Chap. 5.6., → Copper, Chap. 5.7.)

Copper ore concentrates consist mainly of copper pyrites or chalcopyrite ($CuFeS_2$), the most

frequent copper mineral, but may also contain pyrite, bornite, cuprite, chalcocite and others. A typical concentrate composition is 27 % Cu, 28 % Fe, 32 % S. They are processed almost exclusively by pyrometallurgical methods. Pyrometallurgical copper extraction is based on the decomposition of complex iron – copper sulfide minerals into iron and copper sulfides, followed by selective oxidation and separation of the iron portion, and finally oxidation of the remaining copper sulfide. Virtually all the sulfur in the original concentrate ends up as sulfur dioxide. The overall process is conducted in the three discrete stages of roasting, smelting and conversion.

In the roasting stage, the higher sulfide components of the so-called green concentrate are initially decomposed thermally to iron(II) and copper(I) sulfides and elemental sulfur (Eq. 11) [40, 41]. In the prevailing oxidizing atmosphere, this sulfur is instantly converted to sulfur dioxide

$$2\,CuFeS_2 \longrightarrow Cu_2S + 2\,FeS + S \tag{11}$$

$$S + O_2 \longrightarrow SO_2$$

The iron(III) sulfide also undergoes exothermic oxidation. To attain a good separation of iron and copper in the subsequent smelting stage one must ensure that the copper does not become converted to oxide. Therefore, the amount of oxygen is limited so that some of the iron(II) sulfide remains unchanged. Under such conditions magnetite is the predominant oxide (Eq. 12) rather than hematite (cf. Eq. 7)

$$3\,FeS + 5\,O_2 \longrightarrow Fe_3O_4 + 3\,SO_2 \tag{12}$$

The roasted ore, alone or with green concentrate (depending on the concentrate composition and the type of process used), then passes to the smelting stage. Here, in the presence of a siliceous flux, it is heated by the combustion of a fuel, by electricity, or autogenously by oxidation with oxygen to a temperature at which the unconverted sulfides – mainly copper(II) sulfide – are molten. The iron oxide component reacts with the siliceous flux to form a molten slag. Being appreciably less dense, this floats on top of the heavier sulfide phase, known as copper matte. The two can thus be tapped separately.

In the conversion or blowing stage, air or oxygen is blown through the matte in two steps. In the first step (slag blowing), the residual iron sulfide portion is converted to iron(II) oxide, which is removed as a slag from the concentrated matte of copper(I) sulfide. In the second step (copper blowing), the copper(I) sulfide is converted to crude copper (blister copper):

$$Cu_2S + O_2 \longrightarrow 2\,Cu + SO_2 \tag{13}$$

The development of the copper recovery processes during the last few decades has been dominated by two principal objectives. One is the need to economize on energy by making maximum use of reaction heat liberated in the individual process steps. The other is the need to lower the volume and increase the sulfur dioxide concentration of the waste gases as much as possible so as to facilitate environmental pollution control. The trend is increasingly in favor of oxygen technology.

Off-Gas Composition from Specific Process Types. The *reverberatory furnace process* is still used to a considerable extent for smelting copper concentrates, although it suffers from the economic disadvantage of high energy consumption. The design and mode of operation of reverberatory furnaces is described in [42]. Partially preroasted concentrates and green concentrates of low sulfur content are the most frequent feed materials. Copper matte is produced with a copper content about 10 % higher than that of the feed material. The most serious technical disadvantage of this process is the large volume of combustion gas that results from the high consumption of fossil fuels. This dilutes the sulfur dioxide concentration of the total smelter off-gas to ca. 1 – 2 vol %. It is economically scarcely feasible to process this into sulfuric acid.

A comparison of the various pyrometallurgical copper extraction processes from the point of view of the waste gases produced, based on calculations of Schwartz and Eisert [43], emphasizes the problems inherent in the reverberatory furnace process.

By using oxygen-enriched air in oxyfuel burners, the sulfur dioxide content of reverberatory furnace waste gases can be raised to about 6 – 8 vol % and the specific waste gas rate is considerably diminished.

The *electric furnace process* can be used to produce copper matte when electric power is available at low cost. The connected load of such furnaces used in copper metallurgy is up

to 50 MW. The process is in many respects similar to that of the reverberatory furnace except that the specific waste gas rate can be kept relatively low if the furnace is adequately sealed. The waste gas composition depends on the feed material characteristics. The sulfur dioxide content may reach 3 – 10 vol %. Carbon dioxide and carbon monoxide also occur in small concentrations in the waste gas owing to burning of the carbon electrodes.

The *Outokumpu flash smelting process* [44] is one of the standard pyrometallurgical processes used most frequently today. The flash smelting furnace (Fig. 11) consists of an upright cylindrical reaction shaft designed for simultaneous roasting and smelting atop one end of a hearth, over the other end of which is a vertical waste gas shaft. Fine-grained dry concentrate is injected into the reaction shaft with air preheated to 450 – 750 °C or with oxygen-enriched air.

Figure 11. Outokumpu flash smelting furnace
a) Concentrate burner; b) Reaction shaft; c) Settling trough; d) Waste gas shaft

Since the process is not usually autogenous, supplementary heating is necessary, not only in the hearth but also in the reaction shaft, except when oxygen-enriched air is used. In that case, the addition of fossil fuels to the reaction shaft can be dispensed with. The droplets forming in the reaction shaft, consisting of copper matte and slag, accumulate in the hearth, while the gases leave the flash smelting furnace through the waste gas shaft at 1200 – 1300 °C.

Depending on the concentrate composition and the copper concentration of the matte obtained in the flash smelting furnace, about 50 – 70 % of the sulfur content of the concentrate is converted to sulfur dioxide. When operating the furnace without oxygen enrichment, the waste gases contain 10 – 13 vol % of sulfur dioxide, 1 vol % of oxygen, and ca. 0.05 vol % of sulfur trioxide at specific off-gas rates of about 6000 – 6500 m^3/t copper.

Most flash smelting furnaces are operated with reaction air enriched to 45 – 60 % O_2, which substantially reduces the off-gas rate and increases the SO_2 concentration. The relationships shown below are obtained when feeding a concentrate containing 21.9 % Cu, 30.3 % Fe and 32.0 % S.

O_2 content of feed air, vol %	21.0	28.0	31.9	50.0
Inlet temperature of feed air, °C	450	200	25	25
Specific off-gas volume, m^3/t Cu	6016	4593	4087	2363
Off-gas SO_2 content, vol %	13.4	17.8	19.8	28.5

Oxygen has already been used continuously on an industrial scale in the *Inco flash smelting process*. Inco of Canada developed a flash smelting furnace with a daily throughput of up to 1500 t of concentrate. After pretreatment in a fluid bed dryer, the concentrates are injected into the reaction space with 95 % oxygen. The process operates without supplementary heating. The specific off-gas rate is as low as 1090 m^3/t Cu at about 80 vol % SO_2. After adequate gas cleaning, the sulfur dioxide-containing gases are chiefly converted to liquid sulfur dioxide.

The *flame cyclone processes* for intensive smelting with oxygen represent another practical option. On an industrial scale, a combination of a flame cyclone reactor with an electric resistance furnace has been used in the *Kivcet process* developed at the Irtysh metal combine at Glubokoye in the former Soviet Union [45]. The feed material is copper concentrate or complex zinc – lead – copper concentrate, which must be of fine grain size and pourable. Tonnage oxygen is used for the smelting process. The off-gases leave the furnace at about 1250 – 1350 °C. They contain 80 – 85 vol % SO_2. The specific off-gas rate ranges from 800 to 2000 m^3/t Cu, depending on the concentrate composition.

Composition of Converter Off-Gases. Converter processes are generally used for blowing air or oxygen-enriched air through copper matte to convert it to crude copper. The blowing procedure is not continuous, nor are, therefore, the composition and volume of the off-gas. Dur-

ing slag blowing, the sulfur dioxide content of the waste gases at the converter mouth is up to ca. 10 vol %, but during copper blowing it may rise to as much as 20 vol %.

If oxygen-enriched air is used, correspondingly higher sulfur dioxide concentrations are achieved, but precautions must be taken due to the increased generation of heat. However, it is not only the continually fluctuating sulfur dioxide concentrations which are typical of converter processes but also the heavy fluctuations in the gas flow rates.

Because air leaks into the exhaust hoods of the converters, the converter off-gases are diluted considerably. The dilution factors are between ca. 1.8 and ca. 5 [46]. In the *Hoboken syphon converter* (Fig. 12), operated at Metallurgie Hoboken Overpelt in Belgium, air inleakage is effectively avoided [47].

Figure 12. Hoboken syphon converter

Developments to Overcome Off-Gas Processing Problems. All sulfur dioxide-containing gas streams from copper smelting operations, including converter off-gases, must be processed to prevent more than traces of sulfur dioxide entering the atmosphere. The key to successful purification of sulfur dioxide-containing gases to the required standards is continuous stable operation of the purification process, be it a sulfuric acid plant (as is most common at smelters) or some other kind of abatement process. Gas streams which are liable to wide fluctuations in both volume and composition, such as converter off-gases, are quite incompatible with this criterion. These fluctuations can be mitigrated to some extent by conducting the conversion procedure in several converters in a phased sequential operation and combining their off-gases [48]. It is also common practice to mix them with the steadier, more concentrated gas streams from the roasting and smelting stages to produce a combined gas stream within the concentration range needed to maintain autothermal operation of a sulfuric acid plant [49]. As an example, the routing of off-gases from a modern copper smelter incorporating an Outokumpu flash smelting furnace and Pierce Smith [50] converter operation is schematically represented in Figure 13.

Figure 13. Sulfur dioxide production and processing in a modern copper smelter
a) Smelting furnace; b) Waste heat boiler; c) Hot electrostatic precipitator; d) Pierce Smith converter; e) Wet gas cleaning system; f) Sulfuric acid plant

The chief aim of current development work is to unite the individual stages of crude copper extraction into one continuous process, avoiding any discontinuous converter stages. This has been achieved on an industrial scale by Mitsubishi. In the *Mitsubishi process*, the individual process steps are carried out in separate furnaces which are connected with each other via launders to form a continuously operating system [51].

5.5.2. Nickel Smelting (→ Nickel, Chap. 4.)

The mineral used most commonly for nickel production is pentlandite $(Ni, Fe)_9S_8$, which often occurs in conjunction with pyrrhotite (Fe_7S_8) and chalcopyrite ($CuFeS_2$). Nickel flotation concentrates contain 6 – 12 % Ni, 2 – 10 % Cu, 25 – 35 % Fe and 25 – 32 % S.

As in copper metallurgy, the basic operations of nickel extraction are roasting, smelting, and blowing [52].

During concentrate roasting, initially pyrrhotite is oxidized (Eq. 14):

$$3\,Fe_7S_8 + 38\,O_2 \longrightarrow 7\,Fe_3O_4 + 24\,SO_2 \quad (14)$$

Roasting can be performed in sinter machines, multiple-hearth furnaces or, in modern plants, in fluid bed furnaces.

At Inco, at Copper Cliff, Ontario, Canada, ca. 1350 t/d of nickel concentrate are roasted in a *fluid bed furnace* (diameter 5.5 m, height 7.9 m). About 40 000 m^3/h of roasting air is injected through 566 nozzles; the fluid bed has a height of 1.2 m. Roasting proceeds at 650 °C. The roaster gases contain ca. 12 vol % SO_2.

The *Outokumpu flash smelting furnace* yields an off-gas containing 10 – 12 vol % SO_2 when the roasting air is preheated to 500 °C. Oxygen enrichment of the reaction air to 27 – 35 vol % O_2 allows throughput to be increased from 400 to 700 t/d of nickel concentrate and simultaneously raises the sulfur dioxide content in the furnace off-gas to 17 – 18 vol % [44].

A smelting furnace operated by Inco with tonnage oxygen achieves throughputs of 1500 t/d of nickel concentrate. From the furnace off-gases, containing about 80 vol % SO_2, liquid sulfur dioxide is recovered. The annual liquid sulfur dioxide production amounted to ca. 110 000 t in 1970 [53].

The smelting and blowing operations of most process steps of nickel smelting are technically comparable to those of copper metallurgy.

5.5.3. Zinc Blende Roasting (→ Zinc)

Zinc blende (ZnS) is the most important primary material for zinc production. Zinc blende is enriched by flotation to obtain a concentrate with a typical composition of 55 % Zn, 8 % Fe, 32 % S.

The first step in all zinc recovery processes is the roasting of zinc blende to convert zinc sulfide to zinc oxide, simultaneously removing the bound sulfur [54, 55]. In the exothermic roasting reaction, the sulfur is liberated as sulfur dioxide.

$$2\,ZnS + 3\,O_2 \longrightarrow 2\,ZnO + 2\,SO_2 \quad \Delta H = -440\,\text{kJ/mol} \quad (15)$$

To produce a calcine which can easily be leached for electrolytic zinc recovery, which accounts for about 85 % of world production, especially severe demands are made on the roasting process. The calcine should contain not more than 0.3 % sulfide sulfur and 1.8 % sulfate sulfur. The formation of zinc ferrite ($ZnO \cdot Fe_2O_3$), which would disturb the leaching process, must be avoided as far as possible by maintaining constant, optimum roasting temperatures. At the same time, the heat released in the roasting process should be utilized as efficiently as possible in steam generation. Also, to permiteconomic processing of the sulfur dioxide roaster gases, the sulfur dioxide concentration should be kept as high and steady as possible. These requirements can be fulfilled with the aid of fluid bed technology originally developed for the roasting of pyrite.

Vieille Montagne – Lurgi Process. Figure 14 shows the layout of a fluid bed roasting plant for zinc concentrate according to the process of Vieille Montagne and Lurgi, which is nowadays used worldwide [56]. The concentrate, containing ca. 8 % water, is continuously

Figure 14. Vieille-Montagne – Lurgi zinc concentrate fluid bed roasting plant
a) Slinger conveyor; b) Fluid bed roaster; c) Blower; d) Waste heat boiler; e) Cyclone; f) Fluid bed cooler; g) Ball mill; h) Hot-gas electrostatic precipitator

fed into the fluid bed furnace by slinger conveyors. Roasting air is injected through a nozzle grate. The gas velocity in the fluid bed is ca. 0.5 m/s. Cooling elements incorporated in the fluid bed maintain the roasting temperature between 900 °C and 1000 °C. The dissipated heat is recovered in steam generation.

Depending on the composition of the zinc concentrate, the roaster gas at the furnace outlet contains 9 – 11 vol % SO_2 and 5 – 6 vol % O_2. A characteristic feature of fluid bed furnaces is that gas flow rates and gas compositions are relatively constant, which is advantageous from the point of view of subsequent processing. In a downstream waste heat boiler, the roaster gases are cooled to ca. 350 °C and then passed on to the hot gas electrostatic precipitators. About 1 t of high-pressure steam at 400 °C is produced per tonne of concentrate processed.

All other cooling and cleaning operations are as practised in conventional sulfur dioxide gas cleaning systems (see Chap. 6).

The zinc oxide calcine is recovered at various points of the roasting plant in the following approximate proportions:

Fluid bed discharge	20 – 30 %
Waste heat boiler discharge	30 – 40 %
Cyclone discharge	22 – 48 %
Electrostatic precipitator discharge	2 – 5 %

The precise distribution is influenced by the grain size range of the concentrate and by controlled wetting and agglomeration of the concentrate before it is fed onto the slinger belts.

Some characteristic data for the largest zinc blende fluid bed furnace based on the Vieille Montagne – Lurgi process, which has been in operation since 1975 at Electrolytic Zinc in Risdon, Australia [57] are presented below:

Grate area	123 m^2
Furnace volume	2680 m^3
Concentrate throughput (dry)	800 t/d
Roasting air rate	70 000 m^3/h
Roasting temperature	920 ± 20 °C
Roaster off-gas (dry)	67 000 m^3/h
Roaster gas SO_2 content	10 – 11 vol %
Steam generation	1 t/t of concentrate
Steam grade	40 bar/400 °C
Sulfide sulfur in calcine	0.15 – 0.20 %
Sulfate sulfur in calcine	1.4 – 1.6 %

Sanki – Dorr Process. In the Sanki – Dorr fluid bed process, the concentrate is fed to the roaster as an aqueous suspension containing ca. 78 % solids. The fluid bed temperatures are controlled by injecting additional water. This wet feeding method yields substantially less steam than dry feed processes (ca. 0.68 t per tonne of concentrate). It also produces about ten times as much dilute scrubber acid, which must be disposed of [58].

Characteristic data for a Sanki – Dorr plant operating at Mitsui Mining and Smelting, Hiroshima, Japan, are listed below:

Grate area	66 m^2
Furnace height	10.4 m
Concentrate throughput (dry)	250 t/d
Roasting air	18 960 m^3/h
Roasting temperature	930 °C
Concentrate contents	
Zn	50.6 %
Fe	9.6 %
Pb	1.04 %
Cu	0.42 %
Cd	0.28 %
S	30.7 %
Sulfide sulfur in calcine	0.22 %
Sulfate sulfur in calcine	1.63 %

The roasting air is injected into the furnace through 1025 nozzles and the fluid bed is about 1.2 – 1.5 m high.

Oxygen Enrichment. The effect on the throughput of adding oxygen in zinc blende fluid bed roasters has been tested, and several plants are now being operated successfully with oxygen-enriched air. The conditions in the phase diagram of the system Zn – Fe – S – O [59] suggest that there is a limit on the extent to which it is practical to enrich the roasting air with oxygen on account of undesirable sulfate and ferrite formation. According to information from Electrolytic Zinc Co., which has operated a 360 t/d nominal capacity fluid bed furnace with oxygen-enriched air, the optimum was at ca. 24 vol % O_2. By this means it was possible to raise the throughput by ca. 25 % and the sulfur dioxide content of the roaster gases to 12 – 12.5 vol %.

5.5.4. Lead Smelting (→ Lead, Chap. 4.2.→ Lead, Chap. 4.3.→ Lead, Chap. 4.4.)

Lead sulfide ore flotation concentrates, containing ca. 60 % Pb and 17 % S, are roasted almost exclusively in travelling-grate sinter plants.

The oxidation of the lead sulfide is initiated by chemisorption of oxygen on the particle surface; the lead sulfate formed then reacts with the remaining lead sulfide and oxygen to form basic sulfates and, finally, litharge (PbO), releasing sulfur dioxide [60, 61]

$$PbS + 2\,O_2 \longrightarrow PbSO_4 \tag{16}$$

$$PbSO_4 + PbS + 1.5\,O_2 \longrightarrow PbO \cdot PbSO_4 + SO_2 \tag{17}$$

$$PbO \cdot PbSO_4 + PbS + 1.5\,O_2 \longrightarrow 2\,PbO \cdot PbSO_4 + SO_2 \tag{18}$$

$$(x\,PbO \cdot PbSO_4) + PbS + O_2 \longrightarrow (x+2)\,PbO + 2\,SO_2 \tag{19}$$

Metallic lead can be formed in side reactions

$$PbS + 2\,PbO \longrightarrow 3\,Pb + SO_2 \tag{20}$$

$$PbS + PbSO_4 \longrightarrow 2\,Pb + 2\,SO_2 \tag{21}$$

so the sinter product frequently contains entrained lead droplets as well as litharge.

The sulfur dioxide concentrations of lead concentrate roaster gases are in the range 4 – 6 vol % under optimum operating conditions when sintering machines with gas recycling are used.

Sintering roasting of mixed zinc – lead concentrates, as used in the *Imperial Smelting shaft furnace* for simultaneous recovery of zinc and lead, gives only slightly higher sulfur dioxide concentrations of 5 – 7 vol %.

The sulfur dioxide concentration of sintering roaster gases is subject to large and irregular fluctuations and may remain at extremely low levels over extended periods. This makes autothermal operation of a double-absorption sulfuric acid plant difficult. The oxygen content of the roaster gases discharged from the sinter plant corresponds already to more than the required minimum O_2/SO_2 ratio for a contact sulfuric acid plant.

The sulfur trioxide content is influenced to a certain extent by the sintering temperature and by the presence of other materials such as iron oxide. It may amount to as much as 5 – 10 % of the sulfur dioxide content.

The dust content of lead concentrate roaster gases is ca. 5 – 10 g/m^3; in the case of zinc – lead sinter roasting it may even be as high as 20 – 30 g/m^3. Therefore, an efficient gas cleaning system is required. Sinter roasting gases from the processing of flotation concentrates also usually contain varying amounts of hydrocarbons, which originate from additives used in the flotation process. These are only partially burnt in the sintering process, and they pass almost completely through the normal gas cleaning systems, only being oxidized when they reach the dryer of the sulfuric acid plant. The colloidal carbon formed by oxidation colors the acid black. Lighter hydrocarbons even reach the converter, where they burn.

In sintering technology attempts have been made to raise the roasting capacity and increase the sulfur dioxide content of the roaster gas by oxygen enrichment [62]. Although the throughput and sulfur dioxide concentration could be raised by a small extent, there are decisive factors in the sintering process, such as the porosity of the mix and the optimum specific air load for heat transport in the hot sintering zone which limit the increase in throughput [63]. The cost of using technical oxygen is out of all proportion to the potential benefits [39], so this procedure has not been adopted in industrial practice.

Apart from these problems in processing roasting gases with low and fluctuating sulfur dioxide concentrations, dust emissions and dedusting within the sinter plant itself present particular difficulties. Development work on pyrometallurgical lead extraction has, therefore, been directed towards avoiding the complicated sintering process and carrying out the roasting and reduction procedures in a single reaction unit so as to produce waste gases with a higher concentration of sulfur dioxide. *Outokumpu Oy*, for instance, has processed lead concentrates on a pilot scale in a flash smelting furnace, applying principles analogous to those of copper technology. Off-gases with sulfur dioxide concentrations of 11 vol % have thus been obtained [64].

In Italy, a plant for the production of 80 000 t/a lead is in operation based on the *Kivcet process*, which is used in the former former Soviet Union for copper extraction. By using technical oxygen, gases containing 20 vol % SO_2 are obtained from the smelting of lead concentrates.

In the *QSL process* (the Queneau – Schuhmann process as developed further by Lurgi) [65], (see next page, Fig. 15), the lead concentrate is continuously fed into a horizontal cylindrical reactor with flue dust and flux

Figure 15. QSL lead smelting process
a) Mixer; b) Pelletizing disk; c) Reactor; d) Waste heat boiler; e) Hot gas electrostatic precipitator

additives in the form of green pellets. In the oxidation zone the lead sulfide is partially oxidized by injection of technical oxygen (Eq. 22)

$$2\,PbS + 2.5\,O_2 \longrightarrow Pb + PbO + 2\,SO_2 \qquad (22)$$

The lead oxide is taken up by the slag and is reduced by carbon injected into the subsequent reduction zone. The gases leaving the reactor at ca. 1200 °C reach concentrations of 15 – 20 vol % SO_2. QSL plants are in operation in Germany and Korea, with capacities of 75 000 t/a and 60 000 t/a lead, respectively.

5.6. Production by Decomposition of Sulfuric Acid and Sulfates

5.6.1. Waste Sulfuric Acid Processing [66]

Sulfur dioxide-containing gases can be produced by decomposing sulfuric acid. This procedure has been used industrially since 1932 as a means of disposing of heavily contaminated spent sulfuric acid while recovering its sulfur values. The various processes can be classified into two groups [67, 68]. Sulfur dioxide is produced either by thermal decomposition at 800 – 1300 °C or by reducing decomposition at 200 – 600 °C. The input to the process is usually spent sulfuric acid so heavily contaminated with organic substances that it cannot be restored to a useful level of purity by other processes (see → Sulfuric Acid and Sulfur Trioxide, Chap. 4.3.). In some cases the organic contaminants may be of such a nature and be present in such concentration that the acid is more of a sludge than a liquid. In that case it will have a relatively high heating value on account of the impurities, which is advantageous in supplying a portion of the heat required for decomposition. Decomposition is the most reliable way to recover high-grade sulfuric acid or oleum from such wastes, as the impurities are removed completely [69–71].

The sulfur dioxide-containing gases obtained by decomposition of spent sulfuric acid are generally converted back into sulfuric acid in a contact plant after purification (see Chap. 6). The most important prerequisite for a decomposition process, therefore, is that it should generate a gas with a high enough sulfur dioxide concentration for use in a contact plant. This means that it should contain at least 4 vol % of sulfur dioxide after its O_2/SO_2 ratio has been adjusted to the requisite value by addition of air [72]. The sulfur dioxide concentration depends chiefly on the H_2SO_4 content of the waste acid and the heating value of the oxidizable impurities in the spent acid being decomposed.

Thermal Decomposition. Gas-phase thermolysis of sulfuric acid is represented by the overall equation

$$H_2SO_4 \longrightarrow SO_2 + H_2O + 0.5\,O_2 \quad \Delta H = +202\,\text{kJ/mol} \qquad (23)$$

To ensure complete decomposition of the acid and combustion of the organic impurities, decomposition is carried out under oxidizing conditions at ca. 1000 °C [69]. This is a strongly endothermic process, and the more dilute the waste acid the more additional energy is needed to evaporate water before decomposition of sulfuric acid begins. To decompose acid of ini-

tial concentration 70 % at 1000 °C, the theoretical energy requirements are ca. 6.4×10^6 kJ/t H_2SO_4 [69]. About 46 % of this energy is required for dehydration of the 70 % sulfuric acid, evaporation of the water, heating to the maximum boiling temperature of about 340 °C, and evaporation of H_2SO_4. Another 31 % is required for decomposing H_2SO_4 into SO_2, H_2O and O_2; the remaining 23 % is required for heating the decomposition products to the reaction temperature of 1000 °C.

However, this theoretical energy demand of ca. 6.4×10^6 kJ/t H_2SO_4 applies only in the case of indirect heat transfer [69]. Furthermore, there are no construction materials for the heat exchangers that are resistant to corrosion under these reaction conditions. Therefore, the heat required for acid decomposition is in practice supplied directly by means of hot flue gases from the combustion of fossil fuels. Inevitably the heat requirements are far higher than in the case of indirect heating, as the flue gases must be heated to the decomposition temperature (1000 °C). But a large part of the additional heat can be recovered when the gases leaving the decomposition reactor are cooled from 1000 °C to about 350 °C.

The energy requirement for acid decomposition depends mainly on the composition of the spent acid. It rises steeply with decreasing H_2SO_4 concentration in proportion to the amount of water to be evaporated and it is diminished by the heating value of the organic impurities. In the case of dilute spent acids, it is always energetically more favorable to preconcentrate to ca. 60 – 75 % H_2SO_4 so as to separate the bulk of the water before decomposition rather than to decompose the dilute acid directly.

The sulfur dioxide-containing gases produced in the decomposition of sulfuric acid are heavily diluted by the combustion gases introduced for direct heating. However, the amount of flue gas can be substantially reduced by preheating the combustion air. To obtain gases from the decomposition with a high enough sulfur dioxide content for processing in a contact sulfuric acid plant when using fuel oil, the spent acid must contain at least 60 % H_2SO_4 even when the combustion air is preheated to 450 °C.

Another method of reducing external energy input and increasing SO_2 concentrations is the use of oxygen-enriched air.

Figure 16 shows the operation window for the spent acid decomposition process.

Figure 16. Operation window for the spent acid decomposition process

The decomposition of spent sulfuric acid at high temperatures was developed in the 1930s by *Lurgi* [65]. Figure 17 (see next page) shows the flow diagram of a modern spent acid regeneration plant. The decomposition unit itself consists of the empty decomposition furnace and the waste heat boiler system. Downstream of this is a gas cleaning system for further cooling and purifying the decomposition products (see Chap. 6) and a double-absorption plant producing concentrated sulfuric acid and oleum. The application of such an empty decomposition furnace is, however, limited to acids with low residue levels and low organics concentrations that do not result in excess heat beyond the thermal energy requirements of the process.

Spent acid is fed to the top of the vertical, brick-lined furnace and is finely distributed by means of a rotary atomizer [69] specifically developed by Lurgi for atomizing viscous spent sulfuric acid. The atomizing medium is cold air, injected at ca. 1.35 bar. Fuel oil or gas is burnt in several combustion chambers attached laterally to the top of the furnace. The separation of the combustion chamber from the furnace permits complete mixing and combustion of the fuel with the combustion air outside the acid decomposition zone proper. A 10 – 30 % excess of air over the amount actually required for combustion of the fuel is maintained. This is because the amount of oxygen liberated in the decomposition of the acid is not normally enough to burn the oxidizable inorganic and organic components completely. The flue gases enter the furnace tangentially on the same level as the combustion chambers at ca. 1800 °C. A part of their

Figure 17. Sulfuric acid regeneration plant

heat content is transferred to the furnace top by radiation, but the majority is transferred to the acid because of the intensive mixing which takes place in the vortex formed near the outlet openings of the combustion chambers. The furnace temperature of ca. 1000 °C required for acid decomposition is adjusted by controlling the fuel and combustion air rates.

The sulfur dioxide-containing gases leaving the furnace are cooled to ca. 350 °C in an energy recovery system. Depending on the intended use of the recovered energy, different waste heat systems may be used for this purpose. Figure 18 shows three typical decomposition plant concepts with different energy recovery systems [69].

The system in Figure 18 A (analogous to Fig. 17) is designed to produce high-pressure steam (60 – 65 bar). The heat content of the gases emerging from the furnace is used to generate saturated steam. The steam is then heated to ca. 450 °C in a superheater fired by fuel oil. The residual heat of the flue gas is recovered in a gas – gas heat exchanger which preheats combustion air for the decomposition furnace to about 350 °C. Enough high-pressure steam is produced by this system to power a back-pressure turbine drive on the main blower of the downstream sulfuric acid plant, which – as is usual for a "cold gas" plant – does not generate steam of its own. The low-pressure steam exhausting from the back-pressure turbine may be used to provide heat for preconcentrating the spent sulfuric acid.

This process concept is specifically suited for larger plants with capacities > 100 t/d H_2SO_4. It has, for example, been used in a Lurgi-built plant regenerating 360 t/d of 65 % waste sulfuric acid.

In the system of Figure 18 B, the decomposition furnace is followed by a gas – gas heat exchanger, in which the decomposition products are cooled indirectly from 1000 °C to ca. 350 °C. Simultaneously, the furnace combustion air is heated to ca. 450 °C. In general, only about one third of the hot air generated in this heat exchanger is required in the fuel oil burners of the decomposition furnace. The remaining two thirds can be utilized, for instance, for generating steam at 10 bar in a waste heat boiler. A waste heat system of this type has been installed in a twin-stream decomposition plant built by Lurgi for processing ca. 900 t/d of ammonium sulfate- containing spent sulfuric acid resulting from acrylic acid production.

The system of Figure 18 C has the same gas – gas heat exchanger arrangement for cooling the decomposition gas and preheating air as system B. But in this case the surplus hot air at about

Figure 18. Typical sulfuric acid regeneration plant concepts with different energy recovery systems [19]

450 °C is used, along with the dry tail gases of the sulfuric acid plant, for preconcentrating the spent sulfuric acid. In this way, 43 % sulfuric acid can be concentrated to 70 %. The preconcentration unit and the downstream sulfuric acid plant can be integrated so as to allow waste heat from the acid plant absorption system to be utilized for preheating the contaminated acid. In this case spent acid even as dilute as 33 % H_2SO_4 can be concentrated to 70 % using only waste heat [69].

In another decomposition process, developed by *Chemical Construction Corporation* (Chemico) in co-operation with Consolidated Chemical Co. (now *Stauffer Chemical*) [73], the acid is decomposed at 1000 – 1200 °C in a horizontal furnace in which the fuel is burnt directly. For this process, exact control of the oxygen content of the furnace gases is necessary. If the gases contain less than about 2 % free oxygen, there is a risk that sulfur dioxide may be reduced to elemental sulfur, which is precipitated in the subsequent colder parts of the plant. The spent acid is injected through nozzles into the furnace. Acid sludges with a high content of organic impurities are mixed with spent acids from other sources to reduce their viscosity so that they can be atomized more easily.

Spent acids with widely varying physical and chemical properties can be decomposed in the Grillo rotary kiln process. The Grillo process (Fig. 19, see next page) is a multistage decomposition process which is particularly suitable for the decomposition of spent sulfuric acid with widely varying physical and chemical properties.

The Grillo acid decomposition plant consists of a rotary kiln decomposition reactor, a downstream intermediate combustion chamber, and two post-combustion chambers.

The waste acid is injected virtually unpressurized onto a red hot coke bed in the rotary kiln with relatively coarse atomization. The coke bed serves the following three main functions:

1) Uniform distribution of the liquid feed, which offers advantages in terms of reaction rate and uniform reaction conditions
2) Heat storage and regulation

3) Most of the solids content of the waste acid is retained in the coke bed.

Figure 19. Lurgi Grillo decomposition process
a) Rotary kiln decomposition furnace; b) Air preheater; c) Intermediate combustion chamber; d) Post combustion chamber; e) Waste heat boiler

In the rotary kiln, the spent acid is burnt under substoichiometric conditions at 900 – 1000 °C, so that the decomposition gases contain H_2S and COS in addition to CO. By adding combustion air to the intermediate combustion chamber downstream of the rotary kiln, the organic decomposition gas components are completely oxidized at 1250 °C.

Advantages of this process, which is relatively simple to control, are the drastic reduction of the NO_x levels in the decomposition gas, the complete destruction of PCB- containing oils due to the high reaction temperatures, and the retention of the acid-borne solids in the form of coking duff.

Even when using residue oils with high PCB levels as an energy source, this process meets all environmental standards.

For treating spent acids with high residue concentrations dry metal sulfates, and all mixtures of sulfur- containing solids with spent acid, the fluid bed decomposition (Fig. 20) process is particularly suitable.

Figure 20. Decomposition in fluid bed reactor
a) Waste heat boiler; b) Hot electrostatic precipitator

The stationary fluid bed process for sulfate and spent acid decomposition has been successfully employed on a commercial scale for more than 10 years.

A further development of this process is circulating fluid bed technology, which achieves improved decomposition efficiencies due to staged reaction control in the decomposition furnace.

In thermal sulfuric acid and sulfate decomposition, staged process control will gain in significance, as this is the simplest method to suppress NO_x formation. The decomposition temperatures are in the range of 900 – 1000 °C.

Where feasible, the decomposition of spent acids/sulfates can be combined with the roasting of pyrites. The rate at which acid can be processed is limited by the available pyrite roasting reaction heat. When the spent acid is of about 70 % concentration, the ratio of the sulfur dioxide produced from pyrite to that produced from the acid is about 3 : 1. This means that the sulfuric acid output of the downstream plant is four times the H_2SO_4 content of the spent acid feed to the fluid bed reactor. To increase the decomposition capacity of the pyrite roaster, fuel oil, sulfur and oxygen-enriched air may be introduced.

Reductive Decomposition. In a process developed by *Hechenbleickner*, spent sulfuric acid is decomposed at 200 – 600 °C after mixing with a reducing material such as tar sludge or coal. The reduction product is sulfur dioxide, and coke is generated as a byproduct [68]. This process is chiefly used for processing acid sludge from lubricating oil and kerosene production plants associated with oil refineries. In the original process concept, the sludge, which contains up to 50 % organic matter and has a comparatively high calorific value, is fed through a rotary kiln in countercurrent with hot flue gas. The most important variants of this process are known under the names of *Chemico* [73, 74], *Ross – Wilde*, and *Miley* [68]. A further development of the process has been designed to process a wide range of spent acids containing from 0.5 to 60 wt % C and 40 – 90 % H_2SO_4 [75].

In all process variants of the reductive acid decomposition, the sulfur dioxide-containing raw gas obtained contains, besides carbon dioxide and moisture, varying proportions of carbon monoxide and hydrocarbons [68]. Since

the hydrocarbons, especially, are detrimental in a downstream contact plant, generally post-combustion at about 800 °C is required before the gas cleaning stage.

5.6.2. Sulfate Decomposition

Calcium Sulfate. All industrial processes for producing sulfur dioxide-containing gases by decomposition of calcium sulfate, the so-called gypsum – sulfuric acid processes, are based on the *Müller – Kühne process* [76, 77]. In this process the calcium sulfate is decomposed in a rotary kiln at 900 – 1400 °C to give sulfur dioxide-containing gases and cement clinker. The sulfur dioxide is processed to sulfuric acid in an associated contact plant. The clinker is used for making Portland cement, whose sale recovers part of the extremely high costs.

Though originally the raw materials for this process were natural anhydrite or natural gypsum, the process has been employed for decomposing waste gypsum from chemical processes, especially the phosphogypsum, produced as a waste product in the manufacture of phosphoric acid by the wet process (sulfuric acidulation of phosphate rock). In addition, coke is required as a reducing agent and additives such as clay, sand, and iron oxide are needed to convert the lime into a clinker that can be utilized in cement manufacture.

The Müller – Kühne process is based on the reductive decomposition of calcium sulfate [78] with carbon above 700 °C. Part of the calcium sulfate is reduced to calcium sulfide, which reacts above 900 °C with the remaining calcium sulfate to form calcium oxide and sulfur dioxide (Eq. 24 – 26)

$$CaSO_4 + 2\,C \longrightarrow CaS + 2\,CO_2 \tag{24}$$

$$CaS + 3\,CaSO_4 \longrightarrow 4\,CaO + 4\,SO_2 \tag{25}$$

$$4\,CaSO_4 + 2\,C \longrightarrow 4\,CaO + 4\,SO_2 + 2\,CO_2 \tag{26}$$

It is assumed that the reduction to calcium sulfide takes place not as a solid-state reaction but by way of an intermediate stage involving carbon monoxide [79]. The silica-, alumina- and iron-containing additives accelerate the release of the sulfur dioxide by reducing the decomposition temperature and by undergoing side reactions with the calcium sulfate [77]. They also react at 1200 – 1400 °C with the resulting calcium oxide to form cement clinker. The clinker quality depends essentially on exact proportioning of the carbon in relation to the calcium sulfate [78, 80]. Although the stoichiometric molar C/$CaSO_4$ ratio for decomposing calcium sulfate is 1:2, a carbon excess of about 20 % is applied in practice because part of it will burn directly and will therefore not be available for reduction [79]. If not enough carbon is present, the clinker will contain unconverted sulfate and will melt; if there is too much, the clinker will contain sulfide and will disintegrate. Under strongly reducing conditions in the bed, elemental sulfur may form and vaporizes under the prevailing conditions. It can be burnt in the gas phase merely by injecting additional air, but this is undesirable because the nitrogen from the extra air dilutes the sulfur dioxide in the product gases.

The primary materials have to be prepared specifically for the process. Gypsum must first be calcined to remove its water of crystallization and convert it to anhydrite, a process which requires additional energy. The anhydrite, coke, sand, and alumina are finely ground, dried, and fed into a mixer by an automatic metering device. In some cases, the raw meal is pelletized [81]. The average composition is 78 – 80 % anhydrite, 9 – 10 % clay, 4 – 5 % sand, and 6 – 7 % coke. The material is fed in at the upper end of the slightly inclined rotary kiln and passes in countercurrent with the hot gases to the lower, heated end, from which the clinker product is discharged.

The rotary kiln (normally about 70 m long and about 3.2 m inside diameter) is refractory lined with magnesite bricks at its lower end, in the clinkering zone, where a temperature of about 1400 °C prevails. Formerly, pulverized coal was used for heating but those plants which are still in operation preferentially use fuel oil.

The raw gas leaving the kiln at about 350 – 420 °C contains ca. 7 – 10 vol % SO_2, 0.7 – 1.6 vol % O_2, 15 – 20 vol % CO_2, and 23 vol % H_2O [78]. It is efficiently cleaned in a gas cleaning system (similar to those used at roasting plants; see Chap. 6) and is then processed in a contact sulfuric acid plant after addition of enough air to bring the O_2/SO_2 ratio to the required value. The total sulfur yield is about 85 %.

The hot cement clinker leaving the kiln is cooled with air in the clinker cooler and is then ground with about 2 % of added gypsum to ob-

tain the cement product [82]. The attainable quality compares with that of high-grade Portland cement. With this process, cement and sulfuric acid are produced in equal quantities. Per tonne of cement or sulfuric acid, the following raw material quantities are required [77]: 1.6 t anhydrite or 2.2 t natural gypsum, 0.3 t clay, 0.1 t sand, and 0.1 t coke. Furthermore, a total of 9.6 – 11.7×10^6 kJ of energy in the form of fuel oil are consumed. This includes that required in the raw material preparation system.

If phosphogypsum is used, it is much more difficult to produce high-grade cement, and the cleaning of the sulfur dioxide- containing gases is much more complicated than when natural gypsum is used [74]. On account of its high moisture content (up to 40 %), phosphogypsum requires a large amount of calcining energy. The precise contents of residual phosphate and fluoride depend on the phosphoric acid production process and the rock phosphates used, but they are practically always considerably above the very low levels allowable either in cement clinker or in sulfuric acid plant feed gas. Therefore, they have to be removed by a specific, elaborate pretreatment of the phosphogypsum. Material analyses and consumption figures for the *OSW-Krupp process*, developed by Oesterreichische Stickstoffwerke (now Chemie Linz) are shown in Table 2 [77]. Material requirements per tonne of clinker or sulfuric acid are as follows:

Gypsum (as calcined anhydrite)	1.6 – 1.7 t
Clay	0.2 – 0.7 t
Sand	0.1 t
Fuel oil	$11.7 - 13.8 \times 10^6$ kJ

Table 2. Material analyses and consumption figures for the OSW – Krupp calcium sulfate decomposition process [77]

Constituent	wt % in raw meal	wt % in clinker
SiO_2	9.33	19.35

CaO	30.45	63.19
SO_3	42.86	2.00
F	0.15	0.30
P_2O_5	0.50	1.00
C	4.50	0
H_2O	5.26	0

The gypsum – sulfuric acid process was developed by MÜLLER and KÜHNE in Leverkusen, Germany, during World War I, from 1915 to 1917 [76] as a means of making sulfuric acid from indigenous raw materials independent of imports. It has remained of interest in countries with natural gypsum resources where, for strategic or foreign exchange reasons, it is desirable to avoid dependence on imported sulfur. Furthermore, a Müller – Kühne plant operating on recycled phosphogypsum is, in theory, an ideal means of avoiding waste disposal problems in phosphoric acid production. Nowadays, though, its very high capital costs, as well as the cost of its very substantial energy requirement, have made the economics of the Müller – Kühne process so unfavorable as to preclude its use in any but a handful of special cases. The capital costs for a complete gypsum – sulfuric acid plant are about five times as high as those of a sulfuric acid plant based on sulfur combustion. And while the gypsum-based plant is a substantial net energy consumer, a sulfur-based plant produces a substantial energy credit.

The first gypsum – sulfuric acid plant (40 t/d H_2SO_4) operated in Leverkusen from 1916 to 1931. Other plants running on natural gypsum or anhydrite were built in the United Kingdom (Billingham, Widnes, Whitehaven), France (Miramas), Germany (Wolfen, Coswig), Poland, and Austria (Linz) [77]. The French plant shut down as early as 1952 and the plants in Great Britain all closed down in 1972 – 1975. The plant in Linz (230 t/d H_2SO_4) was modified in 1969 to run on phosphogypsum. In 1972, a plant with a capacity of 350 t/d H_2SO_4, processing phosphogypsum according to the OSW – Krupp process, started up at Phalaborwa in South Africa.

Iron(II) Sulfate. Iron(II) sulfate can be decomposed into sulfur dioxide and iron oxide in fluid bed furnaces, multiple hearth furnaces, or rotary kilns [72]. Iron(II) sulfate is obtained in large quantities as its heptahydrate (green salt) during the regeneration of pickling liquors from the metals industry and in the production of titanium dioxide pigment by the sulfate process, [68, 73] which produces 3 – 4 t of green salt for every tonne of titanium dioxide. In 1978, titanium dioxide production capacity in the Western Hemisphere based on the sulfate process amounted to ca. 1.6×10^6 t/a [83]. Disposing of

the enormous amount of co-produced green salt is a major problem. Decomposition is one of the few remaining options for keeping this largely unwanted material from entering the environment.

Iron(II) sulfate heptahydrate is normally separated from sulfuric acid solutions by crystallization. In most cases, it is subjected to preliminary heat treatment to drive off the majority of the water of crystallization before it is decomposed [74], since the direct decomposition of the heptahydrate is energetically unfavorable. In this first treatment step, the heptahydrate is dehydrated at 130 – 200 °C by flue gases in spray dryers or fluid bed dryers to a monohydrate or mixed hydrate of the empirical formula $FeSO_4 \cdot 1.5\,H_2O$ [84]:

$$FeSO_4 \cdot 7\,H_2O \longrightarrow FeSO_4 \cdot 1.5\,H_2O + 5.5\,H_2O \quad \Delta H = 298\,\text{kJ/mol} \tag{27}$$

In the second step, the sesquihydrate is decomposed at ca. 900 °C

$$FeSO_4 \cdot 1.5\,H_2O \longrightarrow 0.5\,Fe_2O_3 + SO_2 + 1.5\,H_2O + 0.25\,O_2 \quad \Delta H = 305\,\text{kJ/mol} \tag{28}$$

Formerly, decomposition was conducted in sintering machines or rotary kilns with coke as reductant [73], and the gases thus obtained contained ca. 7 vol % of sulfur dioxide. Today it is common practice for iron(II) sulfate to be decomposed in a fluid bed pyrite roasting furnace at 850 °C or more. Elemental sulfur, coal, or fuel oil may be used as supplementary fuels [84]. The sulfate is fed in above the fluid bed or iron(III) oxide. The sulfur dioxide-containing gas leaving the furnace is cooled in a waste heat boiler to 350 – 400 °C and is subsequently passed on to the gas cleaning system. The cleaned gases are fed to the sulfuric acid plant. The mixture of metal sulfates and sulfuric acid resulting from the concentration of acid wastes of titanium dioxide production can similarly be processed in a fluid bed reactor [85]. In individual cases, iron(II) sulfate is also decomposed in multiple-hearth furnaces with flue gases from fuel oil or natural gas combustion [72, 85, 86].

5.7. Production from Waste Gases

5.7.1. Combustion of Hydrogen Sulfide

The main source of hydrogen sulfide-containing gases is fossil fuel upgrading. Large-volume gas streams with high hydrogen sulfide contents such as those produced in plants for natural gas purification, in crude oil refineries and in plants for the liquefaction or gasification of solid fuels are in most cases treated by the Claus process to convert the hydrogen sulfide to elemental sulfur (see also → Sulfur, Chap. 6.). With small-volume gas streams such as coke plant off-gases the hydrogen sulfide is burnt to sulfur dioxide, which is converted to sulfuric acid in a wet contact plant. Gas streams which cannot be processed by the Claus process because they contain too little hydrogen sulfide or too high a concentration of gaseous constituents that interface with the Claus process are usually incinerated to oxidize the hydrogen sulfide to sulfur dioxide. Even extremely dilute gas streams, if they contain any hydrogen sulfide or other sulfur-containing compounds such as carbonyl sulfide, carbon disulfide, and thiols, cannot be discharged to the atmosphere because of their high toxicity. The maximum allowable concentration of hydrogen sulfide that can be emitted in Germany, for example, is 10 mg/m^3. The sulfur dioxide-containing gases formed during incineration are either processed to sulfuric acid by special wet catalysis methods or, at very low sulfur dioxide concentrations, are emitted directly.

The hydrogen sulfide-containing gases are burnt with an excess of air:

$$2\,H_2S + 3\,O_2 \longrightarrow 2\,SO_2 + 2\,H_2O \quad \Delta H = -518\,\text{kJ/mol} \tag{29}$$

Depending on the calorific value of the gases and their content of air, the combustion temperature may range from 500 to 1000 °C. The calorific value is a function of the concentrations and the heats of combustion of the hydrogen sulfide and of the oxidizable accompanying compounds such as carbonyl sulfide, carbon disulfide, carbon monoxide, ammonia, hydrogen cyanide, hydrogen, and organic sulfur compounds. In cases where the combustion temperature required for complete oxidation of the noxious substances

cannot be reached, a pilot flame or supplementary natural gas or fuel oil firing must be provided. Gases with a hydrogen sulfide content of 10 vol % or more or with a corresponding calorific value can normally sustain combustion without supplementary firing.

Gases with fluctuating and, especially, extremely low hydrogen sulfide contents cannot be oxidized completely without supplementary heating. For them it is preferable to use catalytic incineration. Special catalysts are available which completely convert all hydrogen sulfide at initiation temperatures of ca. 200 °C. The essential advantage of catalytic incineration over thermal incineration of low-grade hydrogen sulfide-containing gases is that it consumes no additional fossil fuel. This in itself is a saving, and another advantage is that the sulfur dioxide-containing gas formed has a lower moisture content and is not diluted by combustion gases. In addition, the catalyst presents a large specific surface area for the reaction so that the hydrogen sulfide can be completely oxidized with a lower oxygen excess. Therefore a smaller volume of oxidized gas with a correspondingly higher sulfur dioxide concentration is formed.

The sulfur dioxide concentration is determined by the concentration of hydrogen sulfide and other sulfur compounds and the relative volume of air. Where the oxidized gases are destined for subsequent processing to sulfuric acid, the air necessary to provide the required O_2/SO_2 ratio of 1.1 – 1.3 in the contact gases is introduced directly into the hydrogen sulfide combustion zone. Starting from a gas with 20 vol % hydrogen sulfide, for instance, a contact gas with 6 vol % sulfur dioxide is obtained. The water content of the sulfur dioxide-containing gas is inherently high because the oxidation of hydrogen sulfide produces an equimolar quantity of water, to which is added water from the combustion air and water generated by combustion of any other hydrogen-containing substances present in the gas or added as auxiliary fuel.

The hydrogen sulfide-containing gases are normally burnt in a horizontal cylindrical furnace, lined with several layers of refractory bricks and equipped with special safety devices such as explosion flaps, as mixtures of air with hydrogen sulfide in the concentration range 4.3 – 45.5 vol % H_2S are explosive [87]. The hot gases leaving the furnace are preferably cooled in a fire-tube waste heat boiler to generate steam. It must be ensured that the wall temperatures do not fall below the relatively high dewpoint of the moist gases, which is partly determined by the sulfur trioxide content.

5.7.2. Recovery from Flue Gases

The waste gases produced by combustion of sulfur-containing fossil fuels such as coal or crude oil in power stations ("flue gases") have quite low sulfur dioxide contents. The sulfur dioxide content of flue gas from a plant fired by coal containing 1 % S, for instance, is about 700 mL/m^3. Consequently these gases are inherently unsuitable for processing by methods used for treating metallurgical waste gases, for example. However, on account of the large installed power of such stations the volume of flue gas is such that the emission rate of sulfur dioxide is extremely high in absolute terms and is nowadays environmentally intolerable. A 600 MW power station fired with coal containing 1 % S, for instance, emits about 2×10^6 m^3 flue gas containing ca. 4 t/h of sulfur dioxide.

Most industrial countries have introduced exacting regulations relating to environmental protection in recent years, and a large number of dedicated processes for flue gas desulfurization have been developed, some of which are already in use in the industrial countries on a large scale. In most processes, the sulfur dioxide is ultimately converted to calcium sulfate, which is partly disposed of as a waste material and partly utilized in the construction industry. Apart from these, there are the so-called regenerative processes in which the sulfur dioxide is recovered in a concentrated form from the flue gases ("rich gas") or in the form of sulfuric acid (Desonox-process). Typical regenerative processes are the BF process of Bergbau-Forschung and the Wellman – Lord process of Davy McKee (see page 38).

The *BF process* is a dry flue gas cleaning process based on sulfur dioxide sorption on activated coke with thermal regeneration [88]. A simplified flow diagram of this process is shown in Figure 21. The dedusted flue gases from the electrostatic precipitator of the power station are conveyed at about 130 °C to the sulfur dioxide

adsorber, which operates as a moving-bed reactor. The bed is composed of activated coke and moves downwards in crosscurrent with the flue gas. About 80 – 95 % of the sulfur dioxide is adsorbed on the activated coke; simultaneously, residual flue dust is arrested. The cleaned flue gas is drawn through by means of a fan, which discharges into the stack. In contrast to wet flue gas desulfurization processes, in this case the purified gas does not need reheating.

Figure 21. Bergbau-Forschung regenerative flue gas desulfurization process
a) Absorber; b) Coke cooler; c) Regenerator; d) Cyclone; e) Screen; f) Burner

The sulfur dioxide adsorbed on the activated coke is oxidized in the presence of adsorbed moisture by the residual oxygen available in the flue gas. The resulting sulfuric acid is stored in the coke pores. The laden coke is discharged continuously from the adsorber into the regenerator, where it is heated to 600 – 650 °C by the addition of hot sand at ca. 700 °C. The sulfuric acid is decomposed to water vapor and sulfur trioxide. The sulfur trioxide is immediately reduced to sulfur dioxide by the coke, which is itself partly converted to carbon dioxide. Accordingly, the regenerated sulfur dioxide contains substantial amounts of carbon dioxide and moisture.

The regenerator is designed as a moving bed reactor. The mixture of sand and regenerated activated coke discharged at the bottom is separated by means of a vibratory screen. The coke is directly cooled to about 120 – 140 °C by injected water and is recycled to the top of the adsorber. Any carbon losses due to the chemical reaction in the regenerator are compensated by the continuous addition of fresh activated coke. The sand is heated in a fluid bed by combustion of fuel gas and is conveyed pneumatically to the top of the regenerator in the hot flue gases.

Typical analysis values for the rich sulfur dioxide- containing gas discharged from the regenerator are: 25 vol % SO_2, 15 vol % CO_2, 60 vol % H_2O, and traces of N_2, SO_3, HCl, and HF.

The chlorine and fluorine concentrations in the rich gas are about 300 times as high as the concentrations in the original flue gas [88]. Before subsequent processing, the impurities must be removed in a gas cleaning system similar in principle to the type used for cleaning roaster gases (see Section 6.2). The purified and cooled rich gas contains 50 – 60 vol % SO_2 and 30 – 35 vol % CO_2, the remainder consisting of water vapor and nitrogen.

The BF process is suitable for the desulfurization of flue gases with sulfur dioxide concentrations of up to 0.4 vol % [88]. The sulfur dioxide-rich gas produced can be utilized for the production of liquid sulfur dioxide, sulfur or sulfuric acid. In 1974 a large-scale pilot plant using the process was started up in Lünen. It was designed to treat a flue gas volume of about 150 000 m^3/h, the rich gas being processed to elemental sulfur [88].

6. Cleaning of Crude Sulfur Dioxide Gas Streams

6.1. Constituents of Roaster and Metallurgical Gases

The crude sulfur dioxide-containing gases obtained by pyrites roasting, pyrometallurgical nonferrous metal extraction from sulfides, and thermal decomposition of waste sulfuric acid and sulfate must be cooled and cleaned efficiently before being processed to obtain sulfuric acid or liquid sulfur dioxide.

The impurities which may be present can be classified into four categories according to their state of aggregation and the process step of the gas cleaning system in which they are removed [43].

Primary dusts are particles discharged in solid form from the roasting or metallurgical extraction process at the so- called flue dust, purely

mechanically entrained by the waste gases. The proportion and grain size of such impurities depend on the furnace feed and the flow conditions.

Fumes are sublimed substances which are volatilized under the furnace conditions but have resolidified in the form of an aerosol by the time they enter the dedusting system inlet at 300–400 °C. Their grain size is 0.01–2 µm. Frequently they consist of zinc and lead compounds such as zinc oxide and lead sulfate or basic lead sulfate.

Volatiles are substances which are still gaseous when they enter the dry dedusting system but may precipitate in the cold areas of the gas cleaning system. These include arsenic and selenium compounds, mercury, sulfuric acid mists, and hydrocarbons.

Gaseous substances include, for instance, hydrogen chloride, hydrogen fluoride, and lower hydrocarbons. Normally, carbon dioxide and small quantities of carbon monoxide originating from the combustion gases of supplementary heating systems are not harmful.

Whereas the primary dusts and fumes can in most cases be separated mechanically at elevated temperatures in a dry gas cleaning step, the gas must be cooled and passed through a wet cleaning stage to ensure complete separation of the volatile and gaseous impurities.

6.2. Cleaning Systems

The simplified flow diagram of a Lurgi gas cleaning system for sulfur dioxide- containing gases from a fluid bed roasting plant is shown in Figure 22. The same combination of individual process steps is also used for cleaning sulfur dioxide-containing gases produced in other metallurgical processes.

Dry Dedusting. After cooling in a waste heat boiler to 320–400 °C, the furnace waste gases, laden with 50–150 g/m^3 of dust, pass through a cyclone for preliminary separation of the coarse particles. Generally, the collection efficiency is 85–90 % with a pressure drop of about 5–10 mbar.

The majority of the dust remaining in the hot gas is then removed in a hot-gas electrostatic precipitator. The gas passes between two electrodes, one of which (the collector electrode) is grounded and the other (the discharge electrode) is maintained at a sufficiently high negative potential to ionize the surrounding gas molecules, resulting in a so-called corona discharge. Dust particles passing through the corona acquire an electrostatic charge of the same polarity as the discharge electrode and are, therefore, repelled towards the collector electrode, where they are discharged.

Figure 22. Gas cleaning plant (Lurgi system)
a) Cyclone; b) Hot-gas electrostatic precipitator; c) Venturi scrubber; d) Settling tank; e) Pump tank; f) SO_2 stripper; g) "Star" gas cooler; h) Wet electrostatic precipitator

Because corona discharges form much more readily around charged objects which have a very small surface area, and particularly from pointed objects, the discharge electrode is usually in the form of a wire or needle. The collector electrode, however must have as large a surface area as possible to minimize the chances of any charged particles escaping. Hot-gas precipitators are usually of the plate type, in which the gas passes through the channels between a battery of vertically mounted flat collector electrodes. Rows of discharge electrodes are suspended in the gas spaces between the plates. Dust accumulating on the surface of the collector electrodes falls by gravity into a hopper below the precipitator. The applied d.c. voltage between the discharge and collector electrodes is 10 – 80 kV. The specific power requirements are 1.5 – 2.5 kWh/1000 m^3.

Electrostatic precipitators have the considerable advantage of being able to separate more than 99 % of the dust at a pressure drop of $\leq$ 1 mbar. The residual dust content is typically 20 – 200 mg/m^3.

The size and mode of operation of the hot gas electrostatic precipitator depends not only on the volume of gas but also on its dust loading, the size distribution of the entrained particles and, above all, its resistivity. The gas velocity through the unit must be kept below the value at which significant re-entrainment of the discharged particles occurs. The optimum temperature range for operation is determined by the dust characteristics. By means of adequate insulation and temperature control, especially in the "dead" corners, it can be ensured in practical operation that the temperature does not drop below the dewpoint, which would give rise to corrosion by acid condensation [89].

The separated dust is normally recycled to the roasted material handling system.

Wet Separation. The remaining impurities are removed by scrubbing the gases. Adiabatic water evaporation simultaneously cools the gas to 60 – 80 °C so that the major part of impurities such as selenium, arsenic trioxide, and sulfuric acid condense. Some of the impurities are not washed out in the scrubber but remain in the gas in the form of minute solid or liquid particles. These are subsequently removed in wet electrostatic precipitators (see below). Gaseous impurities such as hydrogen chloride or fluoride are also separated in the scrubber, at least in part.

The scrubbing liquid is normally recirculated, so the separated impurities accumulate in it. Solid impurities can be removed as a slurry by sedimentation in a settling tank. Liquid impurities with a relatively low vapor pressure, such as sulfuric acid, increase the acidity of the scrubbing liquid, hence the term wash acid. Part of the wash acid is continuously bled off to hold the concentration in the circuit at or below a maximum of 30 – 50 % H_2SO_4. It is replaced by fresh water and recirculated condensate from the subsequent wet gas cleaning systems. In some cases it may be necessary to bleed the wash acid at a lower sulfuric acid concentration so as to hold the concentrations of other, more volatile impurities such as hydrogen chloride and hydrogen fluoride down to levels at which they are still efficiently absorbed. Arsenic (as As_2O_3) first condenses in the scrubber and then dissolves in the wash acid. The limit of solubility may be exceeded in the circulating wash acid, and crystalline arsenic trioxide can be separated from the supersaturated solution in settling tanks. The discharged wash acid is normally neutralized after air stripping to remove sulfur dioxide.

The scrubbing and adiabatic cooling procedure is usually performed in an unpacked scrubber tower, a Venturi scrubber, a radial flow scrubber, or a combined scrubbing and cooling tower of the Peabody type.

The moisture content of the gases at the temperature at which they leave the scrubber (60 – 80 °C) is too high for production of concentrated sulfuric acid in a contact plant. The gas therefore must be cooled to reduce its moisture content.

Various systems can be used for gas cooling. One method is to pass it through an additional, packed scrubbing tower in which it is cooled by circulating scrubbing liquid. The warm liquid leaving the tower is cooled in a scrubbing acid cooler and is then pumped back to the top of the tower. In another method, the gas is cooled to the requisite gas temperature (30 – 40 °C) in indirect gas coolers (star coolers). The resulting condensate is passed on to the scrubber where it is used for balancing the evaporation losses that occur there.

When the crude gas comes from the roasting or pyrometallurgical treatment of an ore concentrate with a high fluorine content, it may also be

necessary to install a so- called fluorine tower to remove any hydrofluoric acid still present after scrubbing and gas cooling. This tower is packed with a material with a high content of silica, which reacts with hydrogen fluoride to form fluosilicic acid.

The solid and liquid impurities still present in the gas after scrubbing are removed almost completely in wet electrostatic precipitators.

To ensure that no unpurified gas reaches the contact plant, even in case of a wet precipitator failure, two precipitator steps are normally installed in series (primary and secondary cleaning). The two stages together have a collection efficiency of $> 99\,\%$. At the outlet the gas is optically clear when viewed against a light source.

Two patterns of wet precipitator are in use. The older plate type is made of lead. The gas passes along the space between a battery of extremely smooth vertical plates which are the collecting electrodes. The discharge electrodes are suspended between the collector electrodes, from which they are isolated.

Nowadays, though, the plate type of precipitator has practically been replaced by the tube type, in which the collector electrodes are tubular and the discharge electrodes are suspended concentrially inside them. In these precipitators the tubes are made of plastics: the requisite conductivity is attained by preparing the inside of the tube so that the separated acid mist will form a uniform liquid film flowing downwards. In another version, the collection tubes are replaced by a plastic honey comb element.

For the best possible separation effect, the voltage must be maintained – as in the dry precipitators – just below the spark-over voltage of the gas, which may fluctuate, depending on the process. An automatic voltage control system is used for this purpose.

A narrow negative electrode is required only for establishing the corona discharge. The subsequent repulsion of charged dust particles away from the negative electrode is, in fact, more efficient if the electrode diameter is larger and there is no discharge. Some tubular precipitators are therefore designed on a two-stage principle, in which a relatively short corona discharge needle is mounted on the end of a wider, nondischarging electrode rod. There are thus discrete ionization and collection zones [90].

The wet precipitator casing may also be made from plastic, but steel casings with internal rubber-linings or homogeneous interior lead coatings are used as well.

The gas-side pressure drop of such electrostatic precipitators is ca. 2 mbar. The high-tension set requires about 0.8 kWh per 1000 m^3 gas.

The gases at the gas cleaning system outlet must be optically clear (checked by means of a light source) to guard against problems in subsequent processing. Any residual moist mists are difficult to separate, even in the dryer of a sulfuric acid plant, so they may cause substantial operational and corrosion problems.

Mercury Removal. Any mercury contained in the concentrates is volatilized almost completely, passing on to the scrubbing plant as mercury vapor. Depending on the partial pressure, metallic mercury may occur in the scrubbing system, but part of it always remains as vapor in the gas.

As the volatilized mercury still contained in the SO_2 gas will end up in the sulfuric acid production, special gas treatment has to be provided for the removal of the mercury in order to obtain acceptable mercury contents in the acid. Alternatively, if the mercury vapor remains in the gas, the sulfuric acid produced has to be treated to eliminate the mercury.

Both wet and dry methods have been used to remove mercury from roaster gas [91]. Dry methods include filtration through a porous material impregnated with selenium, with which the mercury reacts to form mercury(II) selenide, and activated carbon adsorption. Wet methods include introducing elemental selenium into the wet scrubber of the gas cleaning plant and washing with mercury(II) chloride solution to convert the mercury to insoluble mercury(I) chloride (removed from the scrubbing liquor by filtration). Scrubbing with concentrated sulfuric acid removes mercury in the form of mercuric sulfate.

If mercury is not removed from sulfuric acid plant feed gas, it is absorbed in the drying tower and therefore appears in the product acid. Though a certain amount may be precipitated in the form of mercury(II) sulfate, which can be filtered out, for some purposes it is necessary to purify the acid to a higher standard. One method [91] is to treat the acid in the drying circuit with

thiosulfate, which decomposes to give colloidal sulfur. This in turn reacts with mercury to give insoluble mercury(II) sulfide. Because this technique can only be used when the acid concentration is below 85 %, a preliminary drying tower is installed operating on acid of 70 – 85 % concentration. The main drying tower operates on full-strength product acid.

7. Production of Pure Sulfur Dioxide

One way of producing pure sulfur dioxide is to chemically reduce sulfur trioxide with sulfur. However, since sulfur trioxide is itself usually produced in a sulfuric acid plant processing moderately concentrated sulfur dioxide-containing gases, physical or chemical separation may offer a more direct and attractive route to the pure product. From an economic point of view, the higher the sulfur dioxide concentration is in the raw gas from which it is to be separated the better. Therefore, gases produced by combustion of sulfur or in pyrometallurgical processing of sulfides ores are preferred. But it is possible, by means of regenerative flue gas scrubbing methods, to produce pure sulfur dioxide from low-concentration sources such as power station combustion gases. In view of the very large volumes of these gases that are produced and the current need in many locations to remove their sulfur dioxide content for environmental reasons, this method cannot always be dismissed on simple economic grounds alone.

7.1. Chemical Production from Sulfur Trioxide

Pure sulfur dioxide is formed when sulfur and sulfur trioxide undergo the following weakly exothermic reaction [92]:

$$S + 2\,SO_3 \longrightarrow 3\,SO_2 \quad \Delta H = -99\,\text{kJ/mol} \tag{30}$$

Practical processes using this reaction are distinguished by the form in which the reactants are converted.

Despite its age, the process developed in Germany by *IG Farbenindustrie* [93] is still in use today. Solid sulfur is fed into a reactor containing oleum at ca. 110 °C.

Simultaneously, preheated oleum with 26 – 30 % free SO_3 is fed in at the bottom of the reactor. The oleum rises in countercurrent to the slowly descending sulfur, leaving the reactor at the top with a residual free SO_3 content of 1 – 5 wt %. The sulfur dioxide gas formed in the reactor still contains 5 – 10 vol % SO_3, which is converted to further sulfur dioxide in a column filled with lump sulfur. The last traces of sulfur trioxide are finally removed from the sulfur dioxide by scrubbing with 98 % sulfuric acid. The dilute oleum leaving the reactor flows to the oleum tower of the sulfuric acid plant for reconcentration. As it contains impurities introduced in the sulfur, it must be discharged partially and replaced by fresh oleum.

In modern processes, the sulfur trioxide is not fed as concentrated oleum but in dilute liquid form, and the sulfur is preferably molten. The reaction medium is either oleum of extremely low SO_3 content [94], a liquid mixture of sulfur dioxide and sulfur trioxide under pressure [95], liquid sulfur [96] or oleum of 25 % strength [95].

Figure 23 (see next page) shows the flow diagram of the *Schweizerhall* process [97]. Molten sulfur and liquid sulfur trioxide in stoichiometric proportions are agitated in a reactor with oleum of ca. 25 % strength. The reactor bottom is equipped with a double shell, through which cooling water is pumped to provide temperature control. In normal operation, only slight cooling is required. For start-up, steam heating is necessary. The reaction temperature is adjusted to maintain a sufficiently high pressure of the sulfur dioxide formed that it liquefies in a water- cooled condenser without further refrigeration. The sulfur dioxide leaving the reactor is passed through a secondary reactor filled with solid sulfur, in which the residual sulfur trioxide is converted completely to sulfur dioxide, before entering the condenser. The sulfur dioxide produced by this process is of high purity.

The principal advantages of this process are its relatively low capital cost and the simplicity of operation. The sulfur dioxide production costs are essentially determined by the sulfur price and (especially) the cost of liquid sulfur trioxide, which are normally very high. For 1t of liquid sulfur dioxide, ca. 20 kWh of electric power and around 30 m^3 of cooling water at 20 °C are required.

7.2. Separation from Sulfur Dioxide-Containing Gases

Condensation processes for the production of pure sulfur dioxide are based on the separation of sulfur dioxide from gases by liquefaction. In accordance with the vapor pressure equilibrium between gaseous and liquid sulfur dioxide (see 2), low temperatures, or high pressures, or both are required for this purpose.

In a plant operated by *Bayer*, roaster gases with 6 – 7 vol % of sulfur dioxide are compressed to ca. 5 bar and then passed through a number of countercurrent coolers. These are cooled by liquid ammonia and by the waste gas of the process, the temperature of which has been reduced to − 70 °C by stepwise flashing. The sulfur dioxide content of the waste gas is ca. 0.7 vol % [98]. The energy consumption per tonne of liquid sulfur dioxide of a plant designed for a production of 25 – 30 t/d of liquid sulfur dioxide is ca. 680 kWh.

The so-called *partial condensation* process is quite commonly used. Normally, 30 – 60 % of the fed sulfur dioxide is condensed. Partial condensation plants are frequently operated in connection with sulfuric acid plants, as the residual sulfur dioxide content of the depleted gas is in most cases still relatively high, and so it requires subsequent treatment.

A simplified diagram of this process is shown in Figure 24. The sulfur dioxide is partially condensed under normal pressure by cooling in indirect exchange with an evaporating coolant. The ratio of the volume of liquid sulfur dioxide produced to the residual sulfur dioxide content in the gases is determined by the sulfur dioxide vapor pressure at the condensation temperature, which is controlled in the coolant circuit.

Dry, sulfur dioxide-rich gases are pre-cooled by the cold residual gases in a heat exchanger and passed on to the condenser. The temperature in the sulfur dioxide condenser is held between − 70 and − 40 °C by evaporation of the coolant in the shell. The depleted gases leaving the condenser are passed on to a separator, which removes entrained droplets of liquid sulfur dioxide, and are then conveyed to a sulfuric acid plant or other plant for processing sulfur dioxide after reheating in the gas – gas heat exchanger.

Fluorinated hydrocarbons are mostly used as coolants. The coolant vapor leaving the sulfur dioxide condenser is compressed to the pressure required to restore it to the liquid state after cooling; the exact pressure therefore depends on the temperature of the available cooling water. The liquefied coolant is expanded in several stages to the pressure corresponding to the desired evaporation temperature before being recycled to the sulfur dioxide condenser.

The economics of the partial condensation process are essentially determined by the sulfur dioxide content of the gases; 16 – 18 vol % is the ideal concentration. In a partial condensation plant with 12 vol % SO_2 in the inlet gas and 6 vol % SO_2 in the residual gas, ca. 260 kWh of power and 90 m^3 of cooling water at 20 °C are consumed per tonne of sulfur dioxide liquefied [97].

Figure 24. Liquid sulfur dioxide production by partial condensation
a) Gas heat exchanger; b) SO_2 condenser; c) Expansion valve; d) Coolant compressor; e) Coolant condenser; f) Pump; g) Expansion valve; h) Coolant expansion vessel; i) Liquid SO_2 tank

On account of its economy and operational reliability, the partial condensation process is one of the most frequently used methods of recovering pure sulfur dioxide. It is especially suited for large production capacities. The largest plant built by Lurgi so far, for example, is designed for the production of 160 t/d of liquid sulfur dioxide.

Absorption Processes. In absorption processes, sulfur dioxide is separated from the SO_2-containing gases by reversible absorption into a liquid. This may either be a solvent, in which it dissolves physically, or a scrubbing solution containing a carefully selected active component, to which it becomes loosely and reversibly chemically bound. It is then regenerated in concentrated form by subjecting the rich solution to conditions of temperature and pressure under which the sulfur dioxide is desorbed.

Absorption in Water. One of the oldest absorption processes is atmospheric water washing according to the *Hänisch – Schröder process* of 1884. It is still used today in a modified form, but usually only to recover a part of the sulfur dioxide content of the gas being processed; therefore, it must be associated with some ancillary process to treat the residual gases. For satisfactory operation the crude gas should contain at least 10 – 11 vol % SO_2.

The sulfur dioxide-containing gas is fed into the base of a packed tower and rises in countercurrent with water introduced at the top. The water leaving the bottom of the tower may contain 1 – 2 wt % of sulfur dioxide, depending on the temperature. It is passed to a desorption tower, in which the sulfur dioxide is driven off by low-pressure steam. The water at the exit of the desorber still contains ca. 0.01 wt % of sulfur dioxide. The recovered mixture of sulfur dioxide and water vapor is passed through a water-cooled condenser to remove as much water as possible, after which the sulfur dioxide is dried with sulfuric acid.

The process has relatively high utility requirements: for partial absorption, it uses about 120 m^3 of process and cooling water, 3 t of steam and 90 kWh of power per tonne of liquid sulfur dioxide [97].

A pressurized sulfur dioxide water wash (the *Grillo system*) is schematically represented in Figure 25 (see next page). Purified gas with at least 9 vol % SO_2 is compressed to ca. 5 bar in a compressor. To dissipate the heat of compression, the gas is cooled to about 50 °C in heat exchangers. It is then scrubbed in a water-irrigated packed tower, in which its sulfur dioxide content is reduced to < 0.1 vol %. The residual gas is heated against the compressed fresh gas and subsequently expanded to recover up to 35 % of the compressor energy.

The sulfur dioxide-laden wash water extracted from the absorption tower is first preheated in a liquid heat exchanger and then passed to a desorption column, in which the sulfur dioxide is stripped by injection of low-pressure

Figure 25. Production of pure sulfur dioxide by pressurized water absorption (Grillo system)

steam. The column is connected at the top with a dephlegmator in which the water vapor is disengaged from the sulfur dioxide by irrigation with a partial stream of cold, sulfur dioxide-laden water from the absorption tower. In some cases, instead of the dephlegmator, a separate condensation tower irrigated with water from an indirectly cooled circuit is used. The cooled sulfur dioxide is dried in the same way as in the atmospheric water wash. The wastewater leaving the desorption column sump is used to indirectly preheat the incoming rich scrubbing solution before being discharged.

Even though part of the compression energy is recovered in the expansion unit, the consumption of electric power is extremely high in comparison with the atmospheric water wash. Production of 1 t of liquid sulfur dioxide from a raw gas containing 10 vol % of sulfur dioxide consumes ca. 300 kWh [97]. Furthermore, ca. 1 t of low-pressure steam and ca. 50 m^3 of processed cooling water are required as well.

Both the pressurized and atmospheric water wash processes have the advantage of being able to run on almost any quality of water (except water containing volatile materials).

Absorption in Alkaline Solutions. Alkaline solutions absorb much more sulfur dioxide than water. In some instances strong bases such as caustic soda and ammonia are used, but to an increasing extent these are being replaced by alkaline salts of weak inorganic and organic acids (e.g., sodium carbonate or citrates), or (occasionally) aliphatic or aromatic amines. This is because regenerating the sulfur dioxide is easier and less energy-intensive with these weaker bases. The principle of the process corresponds essentially to that of the atmospheric water wash, except that the absorbing solution is always recirculated from the desorber to the absorber.

In the *Wellman – Lord process* [99, 100], the sulfur dioxide is extracted by means of an aqueous solution of sodium sulfite and sodium hydrogen sulfite. The absorbent is regenerated, and concentrated sulfur dioxide is released by indirect heating with steam in a separate step, which thermally decomposes the sodium bisulfide. The process is chiefly used for desulfurizing flue gases from power stations and tail gases from Claus sulfur plants (see → Sulfur, Chap. 6.), but in a few cases it has also been used for purifying the waste gas from contact (i.e., single-absorption) sulfuric acid plants.

Figure 26 shows a flow diagram of a typical Wellman – Lord plant for flue gas desulfurization. Flue gas which has already been passed through dry electrostatic precipitators or other dust control apparatus is sprayed with water in a saturator section at the bottom of the absorber. This not only cools the gas adiabatically by evaporation of some of the water but also removes any remaining particulates. A bleed stream of the scrubbing water is extracted from the circuit so as to keep the solids content in the circulating liquor down to ca. 5 % and is fed to the wastewater-treatment system. The gas next enters the main absorption zone and is washed in countercurrent with a saturated aqueous solution of sodium sulfite and sodium bisulfite, which is recirculated in several steps. At the top of the

Figure 26. Wellman – Lord process for sulfur dioxide production

absorber, a droplet separator arrests entrained droplets. After reheating to about 140 °C, the moisture-laden flue gas is discharged to the stacks.

The principal mechanism by which sulfur dioxide is absorbed is its interaction with sodium sulfite to form sodium hydrogensulfite

$$SO_2 + Na_2SO_3 + H_2O \rightleftharpoons 2\,NaHSO_3 \qquad (31)$$

In a side reaction, part of the sulfite is oxidized to sulfate by residual oxygen present in the flue gas. Sulfate is also formed to a lesser extent by reaction of the scrubbing solution with traces of sulfur trioxide in the flue gas.

The hydrogensulfite-rich scrubbing liquid is regenerated in a forced-circulation evaporator, indirectly heated by steam. There, the hydrogensulfite is thermally decomposed by the reverse of the absorption reaction (Eq. 31). Some of the moisture content of the saturated sulfur dioxide liberated in the evaporator is removed by indirect cooling with water in the subsequent condenser.

Because the solution becomes oversatured in the evaporator, sodium sulfite is precipitated in crystalline form. The suspension of crystals passes to a thickener, the overflow from which is withdrawn as waste liquor. The slurry of crystals from the underflow is diluted in a tank with condensate and fresh water to extent necessary to turn it back into a saturated sulfite – bisulfite solution. To compensate for bleed losses, sodium hydroxide or carbonate is added.

The sulfates formed in the side reactions mentioned above are not decomposed in the evaporator. To prevent their concentration rising to values at which the absorptive capacity of the solution is impaired and there is a risk of clogging by accumulations of precipitated solids, part of the scrubbing solution is continuously withdrawn from the circuit [99]. The water solubility of the sodium salts in the scrubbing system decreases in the order bisulfite, sulfite, sulfate. The bleed stream is therefore taken off directly after the sulfur dioxide absorber, where the bisulfite concentration is the highest and the sulfite content is the lowest, and is passed through a water-cooled crystallizer, in which crystals consisting mainly of sodium sulfate are precipitated. The sulfate-rich solid is separated in a centrifuge from the residual solution, which is returned to the absorption circuit. The separated solid is dried by indirect steam heating and discharged from the system for further processing [99].

Other Absorption Processes. Sulfur dioxide absorption processes using aqueous amine solutions have the advantage over processes using sodium sulfite – hydrogensulfite solutions that the amine solutions can absorb more sulfur dioxide and the rich solutions can be re-

generated more easily. That is why, in former times, aliphatic and also aromatic amines were used preferably. However, amines are disadvantageous in respect of their vapor pressure, which is high enough for appreciable amounts to be discharged from the absorption system in the cleaned waste gas. Such emissions are today considered detrimental to health, quite apart from having an objectionable odor.

The *Sulfidin process*, commonly used in the past, employed an absorbent consisting of an aqueous solution of xylidine and toluidine. It is no longer used for environmental reasons.

In the United States, a process developed by *American Smelting and Refining Co.*, which uses *N,N*-dimethylaniline, is still used [101].

The *UCAP process* of Union Carbide Corporation was specifically developed for cleaning the tail gases from Claus plants, to which the pure sulfur dioxide is recycled. The absorbent used is an aqueous solution of triethanolamine [102].

During the development of flue gas and exhaust air cleaning processes physical absorption processes have been introduced. An example of such a process for the removal of SO_2 from flue gases or other SO_2-containing gas steams is the *Solinox process* introduced by Linde, in which poly(ethylene glycol) dimethyl ethers are used as absorbent. The SO_2 is recovered in form of a 80 – 90 % SO_2 gas [103].

8. Construction Materials

Dry gases containing sulfur dioxide – and even those containing water vapor as well, if at a temperature safely above the dewpoint – barely attack the steel grades used normally.

Standard steel St 37.2 (material no. 1.0114) and boiler plate HII (material no. 1.0425) are generally preferred. For extreme stress conditions, St 35.8 (material no. 1.1035) or low-alloy steel grades such as St 45.8 (material no. 1.0405) and 15 Mo 3 (material no. 1.5413) are used. Above 550 °C, heat-resistant ferritic (e.g., material no. 1.4713) or austenitic steels (e.g., material no. 1.7841 and 1.7828) are used. On account of their sensitivity to possible traces of sulfur at the furnace outlet, nickel-rich steel grades are not appropriate, especially at elevated temperatures.

For moist sulfur dioxide-bearing gases, especially in gas cleaning plants, lead was the classical material. It can be used at temperatures up to 110 °C and is also resistant to sulfuric acid at concentrations up to ca. 80 %. Lead (DIN 1719) is mainly used in the form of refined copper lead (Pb 99.9 %, Cu 0.05 – 0.08 %; material no. 2.3040) as sheet, castings, or homogeneous lead coatings on steel.

Where there is likely to be thermal cycling stress, antimony-alloyed lead (DIN 28 058) is preferable. The limited creep resistance of lead and lead alloys must be compensated by adequate support. In homogeneous lead coatings, the adhesion of the lead layer is frequently enhanced by initially tinning the steel surface before the lead coating is applied.

Nowadays plastics are normally applied for piping and ducting and for certain other equipment for wet SO_2 gas at moderate temperatures. Plastics such as polyvinyl chloride (PVC), rigid polyethylene (rigid PE) and polypropylene (PP) are chemically resistant to sulfur dioxide, dilute sulfuric acid, and other inorganic compounds which may occur as impurities in the sulfur dioxide gas cleaning system. But with plastics, factors like ageing by sunlight, cold embrittlement, and temperature cycling have to be taken into account. The upper temperature limit for practical application is ca. 60 °C for PVC, ca. 80 °C for rigid PE, and ca. 90 °C for PP, but for composites of these materials with fiberglass-reinforced plastic (FRP), the upper temperature limits are somewhat higher: for FRP/rigid PE, 100 °C, and for FRP/PP, ca. 120 °C. Fluorinated plastics (with or without reinforcement) can be used up to ca. 120 °C.

For wash acids containing sulfur dioxide, lead, rigid polyethylene, and polypropylene are used for piping, pumps, pump tanks, valves, and fittings. With lead, pitting corrosion is likely to occur at higher chloride or mercury contents.

For sulfur dioxide-saturated, dilute wash acids, plastics and silicon-containing cast iron are most often used for valves, fittings, and pumps.

Commercial acid-resistant bricks are used for lining Venturi scrubbers, scrubbing towers, and vessels. For highly fluoride-laden systems, carbon bricks are used.

Impregnated graphite, especially graphite impregnated with phenolic resin, is normally

limited to special applications in heat exchangers, valves, fittings, and pumps.

Special stainless steels are suitable for use in scrubbers, heat exchangers, etc. provided well-defined and stable conditions are maintained. This refers specifically to impurities such as HCl, HF and reducing components, which may disturb the passivating layer on the steel.

9. Industrial Output and Uses

Production for Sulfuric Acid Manufacture. The majority of the sulfur dioxide produced industrially in the world is directly used for sulfuric acid production. Sulfur dioxide requirements for other purposes are relatively small, and they are usually satisfied either by combustion of sulfur at the consumer's works or by pure sulfur dioxide supplied in liquid form. In 1979, for instance, in the Federal Republic of Germany, the consumption for sulfuric acid manufacture was about 3.3×10^6 t SO_2, whereas other uses accounted for only about 40 000 t [104]. In the same year the United States used ca. 23.6×10^6 t of sulfur dioxide for sulfuric acid production and only about 150 000 t for other purposes [105].

Miscellaneous Uses. Apart from sulfuric acid manufacture, sulfur dioxide has uses in the following industrial areas [106, 107].

Paper and pulp industry (→ Paper and Pulp, Chap. 1.3.2.)
Production of cooking solutions for the sulfite pulping process
Reduction of sodium chlorate in the production of chlorine dioxide for pulp bleaching
Pulp treatment after the first (peroxide) stage of a two-stage bleaching process to eliminate hydrogen peroxide before hydrogensulfite treatment
Chlorine scavenger, especially in sulfate pulp factories after the chlorine bleaching step

Chemical and pharmaceutical industries
Production of sulfites, hydrogensulfites, disulfites, thiosulfates, dithionites, and hydroxyalkanesulfinic acid salts
Production of alkane sulfonates by sulfoxidation of sulfochlorination
Production of gelatins and glues
Reductant or solvent
Chemical processing of manganese ores and recovery of, for instance, Co, Se, and Te from waste

Petrochemical and mineral oil industries
Solvent for separation of aromatics from hydrocarbon mixtures (Edeleanu process)
Removal of sulfur-containing impurities from mineral oils
Deodorization of lubricating greases

Textile and leather industries
Bleaching agent

Food and beverage industries
Preserving agent and disinfectant (e.g. sterilization in breweries, fermentation control, and preservation in viniculture)

Sulfur dioxide is also required for water and wastewater treatment. Liquid sulfur dioxide was formerly utilized for refrigerating machines and plants. However, in this area of application it has been replaced almost completely by fluorinated hydrocarbon refrigerants.

10. Analysis

Analytical techniques for sulfur dioxide are covered in literature reviews [108–110].

Qualitative Detection. Sulfur dioxide can be recognized even in extreme dilution by its pungent smell. Solutions of sulfur dioxide, sulfites, or hydrogensulfites decolorize iodine and permanganate on account of their reducing effect. Sulfur dioxide and sulfites are reduced by zinc in a hydrochloric acid solution to hydrogen sulfide, which is readily detected by its smell.

Quantitative Analysis. Sulfur dioxide is determined chemically by iodometry, titrimetry, gravimetry, or colorimetry. On account of the large number of quantitative legal restrictions relating to sulfur dioxide that are now in force, accuracy and reliability are a prerequisite of any analytical method, and definitive procedures and equipment are often laid down by official bodies. In Germany, for example, they are governed by VDI regulations [111–115].

Continuous Monitoring. Routine in-plant performance monitoring usually entails contin-

uous measurement of the sulfur dioxide content of, for instance, roaster gases, contact gases, and tail gases in a sulfuric acid plant by automatic recording analysers, based on a physical property such as spectroscopic absorption in the infrared [114, 116], or ultraviolet [117], or electrical conductivity [115]. Strict adherence to set sampling procedures is essential for accuracy and reliability of in-plant monitoring.

Iodometric Method. REICH's classical, manual iodometric determination is still widely used in industrial practice. A partial stream of the sulfur dioxide- containing gas is drawn through an iodine solution with starch as an indicator until it is discolored. The sulfur dioxide concentration is calculated from the gas volume and the amount of iodine originally present [108]. In another version of the method [111], an excess of iodine is used, and a predetermined volume of the gas is drawn through the solution. The unused iodine is then determined by titration with sodium thiosulfate after addition of starch. Nitrogen oxides interfere with readings from the Reich method; this disturbing influence can, however, be avoided by addition of acetate [108] or aminosulfonic acid [118].

Titrimetric and Gravimetric Methods. For titrimetric or gravimetric determination of sulfur dioxide, the gases to be analysed are passed through a hydrogen peroxide solution, which oxidizes sulfur dioxide to sulfuric acid. This sulfuric acid is either titrated with caustic soda solution against bromophenol blue [112] or is precipitated as barium sulfate and weighed [113]. The analyses are disturbed by other acid or sulfur-containing components. If sulfur trioxide or sulfuric acid are present in the gas, they are removed first by absorption in concentrated sulfuric acid in a wash bottle. On account of the solubility of sulfur dioxide in sulfuric acid, this wash acid must first be saturated with sulfur dioxide.

Colorimetric Method. In the colorimetric determination of sulfur dioxide according to WEST and GAEKE the gas is passed through a solution of sodium tetrachloromercurate [119]. After addition of formaldehyde and *p*-rosaniline, the intensely coloured *p*-rosaniline methylsulfonic acid is formed in a Schiff reaction. The sulfur dioxide concentration is determined by a comparison of the extinction at 548 nm with a calibration curve based on standard solutions.

11. Environmental Aspects and Toxicology

Environmental Aspects. A substantially larger amount of sulfur dioxide than is utilized industrially is produced by the combustion of sulfureous fossil fuels and is discharged into the atmosphere with the flue gases. The calculated total emission of sulfur dioxide from power stations, traffic, households, industry, and trade in the Federal Republic of Germany in 1975 amounted to ca. 3.6×10^6 t [120]. In contrast, only about 2.7×10^6 t were used for that year's sulfuric acid production of ca. 4.2×10^6 t H_2SO_4 [121]. In the last years the SO_2 emissions from power plants in Germany have been reduced continuously with the installation of flue gas desulfurization plant and with the utilization of low-sulfur fuels, but emissions from traffic, households, industry, etc. in 1990 still account for 620×10^3 t/a. Emissions from power stations amounted to 320×10^3 t/a. For worldwide atmospheric emissions, only rough estimates are available. For 1970, while global emissions were estimated at 157×10^6 t SO_2 [122], only about 61×10^6 t were consumed in the production of ca. 94×10^6 t of sulfuric acid [121].

Large-scale emission of sulfur dioxide close to ground level has indisputably been the cause of some spectacular environmental problems in the past. A large area around Sudbury, Ontario, was completely sterilized by sulfur dioxide from primitive ore roasting operations around the turn of the century, and much of it is still barren as a result of the ensuing soil erosion. Calamitous sulfuric acid fogs occurred in Donora, Pennsylvania, and London, England, in 1948 and 1952, when adverse climatic conditions prevented sulfur dioxide from industrial sources and domestic coal fires from dispersing. The causes of these episodes were correctly identified, and the action taken to control ground level smoke and sulfur dioxide concentrations has effectively prevented them from recurring. In the case of industrial sources, however, this has often been achieved by merely building taller chimneys to disperse the sulfur dioxide over a wider area, and as the consumption of fuels has increased over the years it has been argued that the problem has merely been shifted from the location where

the sulfur dioxide is produced to other locations downwind.

Considerable publicity has been given to the apparently increasing problem of acid rain, and there does, indeed, seem to be a correlation between the incidence of acid rainfall and the atmospheric transport of pollutants from major industrial locations [123–127]. Establishing in any degree of certainty to what extent sulfur emissions are responsible for acid rain is, however, complicated by incomplete knowledge of the magnitude of sulfur emissions from natural sources, the atmospheric chemistry of sulfur, and the importance of other potential acidulants such as nitrogen oxides. It is also, unfortunately, hampered by politics, particularly in those cases where there is a possibility that pollution from one country could be contributing to acidic rainfall in another [128, 129]. Much of the research is being conducted by or for national agencies which have the power to publish or play down the results as may be expedient. No government purporting to be dedicated to the topical causes of controlling inflation and combatting unemployment at home will lightly order a major programme of sulfur dioxide emission control, with its almost devastating economic implications, just for the purpose of ameliorating the environment in some other country if there is yet room for argument. Nevertheless, the evidence linking sulfur dioxide pollution to acid precipitation has been mounting gradually [130, 131]. A report by the U.S. National Academy of Sciences, for example, has stated that there appears to be a direct proportionate relationship between sulfur dioxide pollution and the amount of acidic sulfates in precipitation [132].

Toxicology. Ill-effects of sulfur dioxide on humans and animals are mainly related to irritation and damage of the moist mucous membranes by the formation of sulfurous acid. The odor threshold of sulfur dioxide in air is between 0.3 and 2.5 ppm. In most human beings, concentrations of 5 – 10 ppm will lead to irritation of the respiratory tract; in sensitive people they may produce spasms of the bronchi. Higher concentrations will cause heavy irritative coughing, while breathing sulfur dioxide at concentrations above 400 – 500 ppm, even for only a few minutes, is dangerous to life. The maximum workplace concentration is defined as 5 ppm (14 mg/m^3).

Long-term exposure may possibly lead to bronchopneumonia and, in extreme cases, to toxic pulmonary edema with dyspnoea, cyanosis and cardiac-circulatory failure. Short-term exposure to extremely high concentrations may cause glottal spasm, gasping or inability to breathe. Symptoms experienced after long-term exposure are loss of appetite, constipation, loss of taste, red tongue, convulsions, eye inflammation, emphysema and nasal and bronchial mucus secretion, which may be blood-stained. Contact with liquid sulfur dioxide causes extremely painful conjunctivitis, conjunctival edema and opacity of the cornea in the eye as well as frostbite on skin and mucous membranes.

Aqueous sulfur dioxide solutions (sulfurous acid) may burn eyes and skin. Swallowing, which is rather improbable on account of the intense warning smell, may cause irritation or burns in the esophagus and stomach, depending on the quantity and concentration swallowed, followed by nausea, gastric pains, vomiting, and diarrhoea. Sulfurous acid absorbed by the body is converted to sulfate and discharged in the urine, as evidenced by an increase in urine acidity.

Effects on Vegetation. Plants are impaired by sulfur dioxide at even lower concentrations than human beings. Sulfur dioxide levels of 1 – 2 ppm are enough to cause acute damage to the leaves of plants in only a few hours, followed by necrosis, probably resulting from impaired photosynthesis. For protection of the environment, the BimSchG law in Germany lays down the following emission values: 80 µg/m^3 related to a dust value of more than 150 µg/m^3, and 120 µg related to a dust value of less than 150 µg/m^3.

Further information on the toxic effects of sulfur dioxide is available in publications [107, 133–136].

1. Introduction

Sulfur dyes have been used for dyeing cellulose fibers since their discovery over 100 years ago. Dyeing cotton and blends thereof with synthetic fibers remains their main application. Sulfur dyes are also used for paper, but to a much lesser extent. A special form of sulfur dyes is used for the fast-dyeing of certain types of leather, but in comparatively small quantities.

From the dyeing aspect sulfur dyes are similar to vat dyes. Unlike vat dyes, which can generally be dissolved in water only with strong reducing agents such as sodium dithionite/sodium hydroxide, sulfur dyes are preferably dissolved with weak reducing agents, especially sodium sulfide or the combination glucose and sodium hydroxide.

The reduced sulfur dyes become attached to the cellulose fiber from hot aqueous solutions because of their pronounced substantivity. Like the reduced vat dyes, they are fixed on the fiber in the insoluble oxidized form by the action of oxidizing agents.

Compared with other classes of dye, the sulfur dyes mainly color cellulose fibers in muted shades. Their advantage lies in the inexpensive production of deep colorations with good fastness properties, particularly in the shades black, navy blue, blue, brown, yellow-brown, olive, and dark green. The development of various commercial forms allows sulfur dyes to be adapted well to modern high-performance dyeing processes.

The following discoveries were milestones in the development of this class of dyes:

1873: Sulfur Brown 1 [*1326-37-0*], made by heating sawdust or other lignin-containing substances with sodium polysulfide (Croissant and Bretonnière), still on the market.

1893: Sulfur Black 3 [*1326-81-4*], made by heating 4-aminophenol with sodium polysulfide. Other sulfur dyes were obtained by heating benzene and naphthalene derivatives with sodium polysulfide (Vidal).

1897: Sulfur Black 9 [*1326-97-2*], made by heating 2,4-dinitro-4′-hydroxydiphenylamine with sodium polysulfide (Kalischer). Under the name Immedial-Schwarz V, it was the first sulfur dye to compete with Aniline Black.

1899: Sulfur Black 1 [*1326-82-5*], made by heating an aqueous mixture of sodium 2,4-dinitrophenolate and sodium polysulfide (Priebs and Kaltwasser). Still irreplaceable in terms of cost.

1900: Sulfur Blue 11 [*1326-98-3*], made by purification and oxidation of Sulfur Black 9 (Bertschmann). Discovery of the possibility of producing brightly colored sulfur dyes by boiling indoaniline derivatives with sodium polysulfide solutions (von Weinberg and Herz).

1902: Sulfur Blue 7 [*85586-03-4*] from the indoaniline of 2-aminotoluene (Herz). Sul-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a25_613

fur Blue 13 [*1327-59-9*] from the indoaniline of diphenylamine (Herz). Sulfur Orange 1 [*1326-49-4*], made by heating 2,4-diaminotoluene with sulfur (von Weinberg).
1904: Sulfur Green 2 [*1327-74-8*], made from the indoaniline of 8-phenylamino-1-naphthalenesulfonic acid (Böniger).
1907: Sulfur Red 6 [*1327-85-1*], made from 8-amino-7-methylphenazin-2-ol (Lehmann).
1909: Vat Blue 43 [*1327-79-3*], made from the indoaniline of carbazole (Haas and Herz). This dye colors cellulose fibers best from the dithionite vat and is more resistant to chlorine than most sulfur dyes. It was sold under the name Hydron-Blau R and since then has competed with indigo. It is an important commercial product, which is described in the literature as a sulfur vat dye because of the similarity between its properties and those of vat dyes.
1911: Sulfur Black 11 [*1327-14-6*], made from 4-(2-naphthalenylamino)phenol [*93-45-8*] (Heimann). It was introduced on the market in 1926 under the name Indocarbon CL and is mainly used in combination with Vat Blue 43 because of its similar properties.
1935 – 1938: Sulfur Brown 52 [*1327-18-0*] from decacyclene. Sulfur Brown 60 [*1327-20-4*] and Sulfur Brown 51 [*1327-22-6*] from polynitro derivatives of decacyclene (Hagge and Hagen).
1940: Sulfur Green 14 [*12227-06-4*] (clear green) was the first sulfur dye to be synthesized by conversion of tetraamino copper phthalocyanine into tetrathiocyanato copper phthalocyanine (Haddock). Dyes based on copper phthalocyanine on the market are substituted with thiolate groups.
1941: Sulfur Red 14 [*81209-07-6*]: perylene pigment with structure (**1**), substituted with two thiocyanate groups, currently on the market.

1

The sulfur dyes discovered subsequently have remained relatively unimportant.

2. Chemical Properties

The insoluble conventional sulfur dyes are macromolecules cross-linked via di- and polysulfide bridges. They are amorphous and practically insoluble in all solvents. The di- and polysulfide bridges are the reactive groups, which, after reduction to thiolate groups, result in water-solubility. Addition of acid causes the precipitation of the water-insoluble thiol form.

Sulfur dyes that contain the quinoneimine structural element (see Section 3.2.3), undergo a color change on reduction.

The most commonly used reducing agents are sodium sulfide; sodium hydrogen sulfide and sodium carbonate; glucose and sodium hydroxide; and sodium dithionite and sodium hydroxide.

Through the action of mild oxidizing agents (e.g., air), the insoluble sulfur dyes are regenerated on the fiber. Strong oxidizing agents can oxidize the di- and polysulfide bridges of the insoluble sulfur dyes to sulfonic acid groups [5].

Some sulfur dyes form complexes with heavy metal ions. Copper-containing commercial products were previously available, which differed considerably in shade from the copper-free dyes. Apart from the copper phthalocyanine derivatives, these copper-containing dyes are no longer made by the leading producers for ecological reasons.

3. Classification and Structure

3.1. General

Sulfur dyes with a constitution number are defined in the Colour Index by the starting materials, the type of sulfurization, and in some cases the type of work-up. These definitions naturally cannot be precise and were therefore only chosen because little is known about the structures of sulfur dyes.

Even in sulfurization of a defined compound the sulfur dye formed consists of a mixture of products, because sulfurization involves various reactions, including substitution, ring-formation, reduction, and oxidation. The mixture contains positional isomers as well as compounds with different sulfur contents and degrees of condensation. The composition and properties of a sulfur dye depend on the nature and the composition of the sulfurization agent, on the ratio of sulfurization agent to starting material, on the ratio of the starting materials to one another (for two or more starting materials), on the reaction medium, on the reaction conditions, on the method of work-up, and sometimes on the subsequent treatment. Commercial products of higher value are the result of extensive optimization.

3.2. Classification

The classification of sulfur dyes according to the type of sulfurization has become the established method.

Table 1 gives examples of the different types of sulfur dyes.

3.2.1. Sulfur Bake Dyes

Sulfur bake dyes are obtained by heating a starting material with sulfur at 200 – 350 °C. The products are yellow, yellow-brown, orange-brown, or olive. The most important starting materials are 2-(4-aminophenyl)-6-methylbenzothiazole (**2**), 2,4-diaminotoluene, 1,4-diaminobenzene, and decacyclene [*191-48-0*] (**3**).

2

3

In the case of starting materials that contain amino and methyl groups the color of the dye originates from the formation of the benzothiazole ring system.

On investigating Sulfur Orange 1, produced from 2,4-diaminotoluene, Zerweck et al. found that ca. 6 – 8 benzene rings are bonded via annelated thiazole rings (**4**) [6].

4

It is, however, not known what gives rise to the intensive orange-brown color of Sulfur Brown 52, which is obtained by baking decacyclene with sulfur.

3.2.2. Polysulfide Bake Dyes

Polysulfide bake dyes are obtained by evaporating a mixture of the starting materials with aqueous sodium polysulfide solution and subsequent heating of the thickened material to >180 °C. This method dominated sulfur dye production in the initial phases. Some of the sulfur dyes produced in this way are derived from inexpensive nitro compound starting materials, which are reduced to amino compounds in aqueous media before baking. Dye formation then takes place as with sulfur bake dyes. An example is Sulfur Brown 8 [*1326-41-6*] obtained from 2,4-dinitrotoluene.

In some cases the amino group is already present in the starting material or the starting materials are free of nitrogen. Examples are Sulfur Brown 16 [*1327-12-4*] obtained from 5-amino-1-naphthol, and Sulfur Brown 1 [*1326-37-0*] from lignin.

3.2.3. Polysulfide Melt Dyes

Polysulfide melt dyes are produced below 180 °C in a suspension which can be stirred until sulfurization is complete. Compounds with the general formulas (**5**), (**6**), or (**7**), which contain or can form the quinoneimine structural element, are mainly used as starting materials.

Table 1. Examples of sulfur dyes

Starting materials	Colour Index Generic name	Specification Constitution number	CAS registry no.
Sulfur bake dyes			
	Sulfur Orange 1	53050	[*1326-49-4*]
	Sulfur Brown 21	53065	[*1326-54-1*]
	Sulfur Green 12	53045	[*1326-48-3*]
	Sulfur Brown 52	53320	[*1327-18-0*]
Polysulfide bake dyes			
	Sulfur Brown 8	53020	[*1326-41-6*]
	Sulfur Brown 46	53015	[*85940-08-5*]
	Sulfur Brown 16	53285	[*1327-12-4*]
	Sulfur Green 11	53165	[*12262-52-1*]
Polysulfide melt dyes			
	Sulfur Black 1	53185	[*1326-82-5*]
	Sulfur Blue 11	53235	[*1326-98-3*]

Table 1. (Continued)

Starting materials	Colour Index Generic name	Specification Constitution number	CAS registry no.
	Sulfur Blue 7	53440	[*85586-03-4*]
	Sulfur Blue 13	53450	[*1327-59-9*]
	Vat Blue 43	53630	[*1327-79-3*]
	Sulfur Red 10	53228	[*1326-96-1*]
	Sulfur Black 11	53290	[*1327-14-6*]
	Sulfur Green 2	53571	[*1327-74-8*]
	Sulfur Red 6	53720	[*1327-85-1*]

5

6

7

8

As an alternative to the quinoneimines the more stable aminohydroxy compounds (**8**), formed by reduction of quinoneimines, are used.

Sodium sulfide is generally used for the reduction of the quinoneimines. The indoaniline derivatives for the dyes Sulfur Blue 7, 10, and 13, and Vat Blue 43 are produced by condensation of aniline derivatives with 4-nitrosophenol (tautomer: 1,4-benzoquinone oxime) [*104-91-6*] in 70–95 % H_2SO_4 at −25° to +10 °C.

The reaction rates depend on the nature of the aniline derivative, the sulfuric acid concentration, and the temperature [7].

The indoaniline derivative for Sulfur Green 2 is produced by oxidizing a mixture of 4-aminophenol and 8-phenylamino-1-naphthalenesulfonic acid.

The polysulfide melt class encompasses the most important sulfur dyes. Sulfur Black 1 [*1326-82-5*] is formed by heating sodium 2,4-dinitrophenolate in water with sodium polysul-

fide. Most of the nitro groups are reduced. During sulfurization, which occurs on prolonged heating, ammonia is formed besides hydrogen sulfide. For every 3 mol dinitrophenolate used 1 mol ammonia is formed [8], which agrees with the N : C ratio of ca. 5 : 18 in Sulfur Black 1. The S: C ratio in Sulfur Black 1 appears to be generally independent of the sulfurization conditions and to be fairly constant if sulfurization has been carried out until maximum color yield is reached.

The suggested structures published so far do not correspond to the N : C ratio of Sulfur Black 1 [3]. Its constitution is still unknown. The speculative structural formulas **9** and **10** are in good agreement with the elemental ratios found, if oxygen is disregarded.

9

10

With regard to the constitution of the sulfur dyes from compounds with the general formula (**6**), sound ideas concerning important structural elements have been derived from investigations.

Sulfur Blue 9, obtained by sulfurization of the indoaniline derivative (**11**), has a phenothiazinone structure. Degradation of the dye with bromate and hydrobromic acid gave the brominated product (**12**), which was identical with the product formed by bromination of Methylene Violet (**13**) [9].

11

12

13

ZERWECK et al. prepared the thianthrene compounds (**15**) from the phenothiazone derivative (**14**), in which the three free positions of the quinoid ring are occupied by chlorine atoms, by stepwise substitution, condensation, and substitution. The compounds (**15**) are very similar in their properties to the sulfur dyes produced from the corresponding indoanilines by the polysulfide melt method [9].

14

15

It is therefore assumed that the thianthrene compounds (**15**) are also formed in the polysulfide melt. The ratio of elements found in the quinoneimine sulfur dyes indicates that connection of two or more quinoid rings by sulfide or sulfoxide bridges must be involved to a considerable extent.

The Sulfur Blues 7 and 13, Vat Blue 43, Sulfur Black 11, and Sulfur Green 2 belong to the quinoneimine sulfur dyes from indoanilines of the general formula **6** (Table 1).

The quinoneimine sulfur dyes derived from compounds with the general formula **7** are no longer commercially available apart from the red-brown Sulfur Red 6 (Table 1).

3.2.4. Water-Soluble Sulfur Dyes

Sulfur and polysulfide bake dyes and polysulfide melt dyes can be converted into water-soluble thiosulfate esters by sulfite and atmospheric oxygen:

$$\text{D-S-S-D} + 2\,HSO_3^- + 1/2\,O_2 \rightarrow 2\,\text{D-S-}SO_3^- + H_2O$$

3.2.5. Dyes Not Produced by Sulfurization

The classical sulfur dyes, which do not include a red or a clear green, are complemented by two dyes with clear red and clear green shades, not produced by sulfurization.

Sulfur Red 14 with structure (**1**) [*67923-45-9*] behaves like a sulfur dye and dissolves in water in the presence of sodium sulfide with cleavage of the thiocyanate groups to give thiolate groups. Leuco Sulfur Green 36 [*68511-01-3*] is a copper phthalocyanine substituted with thiolate groups.

4. Production

4.1. Sulfur and Polysulfide Bake

In these methods of sulfurization the reaction mixtures become highly viscous to unstirrable during the course of the reaction. Special types of reactor are used to lower the temperature gradient in the melt so that the dyes achieve high color yields and acceptable quality.

Baking crucibles, heated by a heat-transfer medium and equipped with efficient stirring and comminuting equipment are in use, as are horizontally rotating steel drums heated with combustion gases. In the steel drums, steel rods or balls act as stirrers.

A twin-screw reactor has been proposed for the continuous production of the sulfur bake dye based on 2,4-diaminotoluene with addition of ammonium carbonate [10].

After sulfurization is complete, the contents of the reactor are cooled under nitrogen, comminuted, and dissolved in hot, aqueous sodium sulfide solution. If the sulfurized material contains sufficient excess sulfur, it is preferable to boil it with aqueous sodium hydroxide solution. The excess sulfur disproportionates into sodium sulfide and sodium thiosulfate, the former effecting dissolution of the dye. The solution is purified and oxidized with air, converting excess sulfide to thiosulfate. The precipitated dye is filtered off and processed to give the desired commercial form.

4.2. Polysulfide Melt

In polysulfide melt sulfurization, which is carried out with sodium polysulfide in water or other solvents, the reaction mixture remains stirrable throughout the reaction. Stainless-steel, steam-heated, stirred vessels are used as reactors. The condensate can be recycled or discharged.

Besides water, alcohols which are immiscible with water but can be steam-distilled are used, in particular *n*-butanol, or a glycol ether – water mixture. Monoethers of ethylene glycol or diethylene glycol, especially diethylene glycol monoethyl ether (carbitol), are frequently used. An alkali-stable hydrotrope (e.g., sodium xylenesulfonate) is generally added to glycol ether melts. The reaction temperature in the carbitol – water mixtures can be adjusted to a desired value in the range 105 – 140 °C by distillation and be maintained by changing to reflux. This operating procedure and the addition of a hydrotrope gives uniform sulfurization with advantages in terms of color yield and quality.

When dye formation is complete the alcohol is recovered by steam distillation. The partially dissolved dye is generally completely precipitated from the aqueous suspension by air oxidation, filtered, and washed. In some cases it is salted out with salt water. The filter cake is then further processed to the desired commercial form.

There is also the possibility of converting reacted glycol ether melts into preparations ready for use as dyes by adding of reducing agents and water.

5. Environmental Protection

Wastewater. The main salt present in the wastewater from sulfur dye production is sodium thiosulfate. It is formed as a side product of sulfurization with sodium polysulfide, and also from the oxidation of excess sodium polysulfide by atmospheric oxygen. It is also formed during alkaline work-up of sulfur and polysulfide bakes (Section 4.1). Sodium polysulfide is also present in the waste water if the corresponding dyes are isolated by salting out instead of by air oxidation. In some cases sodium sulfite is also present.

Filtrates which mainly contain sodium thiosulfate are treated with sulfuric acid under pressure at temperatures above 130 °C [11]. This disproportionates the thiosulfate to sodium sulfate and elemental sulfur:

$$3\,Na_2S_2O_3 + H_2SO_4 \rightarrow 3\,Na_2SO_4 + 4\,S + H_2O$$

The sulfur is separated and fed back into the production process.

Polysulfide-containing filtrates are mixed with thiosulfate- and sulfite-containing filtrates and then treated with sulfuric acid, so that elemental sulfur is formed [11]. The reaction is controlled so that neither hydrogen sulfide nor sulfur dioxide is liberated and the wastewater only contains sodium sulfate and small amounts of sodium thiosulfate.

Off-gas. Hydrogen sulfide is formed during sulfurization. It is completely absorbed by sodium hydroxide forming sodium hydrogensulfide, which is recycled to the production process or is used as a reducing agent in the dyeing process.

Wastewater from Dyeing Works. In the wastewater from the dyeing works the concentrations of the sulfur dyes are generally low because of their high substantivity and good bath exhaustion. Besides dye residues, it contains the excess sulfide from the dyeing process and downstream products from the oxidizing agents used in the fixing process.

To remove the sulfide, the wastewater is subjected to air oxidation, whereby sulfide is oxidized to thiosulfate. For dyeing works where it is not possible to aerate the wastewater, the use of low-sulfide sulfur dye preparations or sulfide-free finely dispersed commercial forms together with sulfide-free reducing agents solves this problem.

In the case of oxidizing agents, chromate, bromate, and Chloramin T no longer need be used, so that chromate- and AOX-free wastewater is produced. Hydrogen peroxide is the oxidizing agent of choice.

6. Commercial Forms

Powders, the oldest commercial form, consist of dried and ground press cake, standardized with sodium sulfate, sodium chloride, or sodium carbonate. Before application the powder is stirred in water, boiled with the reducing agent, diluted with water and cooled.

In the last few decades, more readily handled forms, which are better adapted to modern dyeing methods, have come on to the market and have extensively replaced the old powder forms.

To produce *low-dust granulates*, press cakes are reduced in concentrated form, mixed with a dispersing agent, and dried in special equipment. These products can be readily dissolved or dispersed in cold water.

To produce *liquid dispersions*, press cakes are slurried with water and dispersing agents and ground in bead mills.

Finely dispersed powders are produced by spray drying liquid dispersions.

Liquid preparations of reduced sulfur dyes are available in a ready-for-use form containing sodium sulfide and sodium hydrogensulfide, and in a low-sulfide form for dyeing with alternative reducing agents. They are produced by dissolving press cakes or reacted melts in water together with the reducing agents commonly used for sulfur dyes. By adding hydrotropic agents, relatively concentrated stable solutions can be obtained. If dyeing is carried out with the low-sulfide form, reducing agent must be added to the dyeing bath to achieve full color strength.

The *water-soluble sulfur dyes* are thiosulfate esters. They are sold as aqueous solutions or in dried form. They have no affinity for the cellulose fiber and are first reduced to the leuco form, which exhibits fiber affinity. This makes them very versatile and they are particularly advantageous where uniform dyeing of an article is only achieved by an excellent penetrating capacity because the packing density is high.

7. Quality and Analysis

To assess the quality of sulfur dyes the technical properties are decisive as in all classes of dyes. The comparison of the color shades and color strengths of the colorations produced under standardized conditions is carried out at differing depths of color visually and by colorimetry. With suitable toning dyes, correction of small deviations in color shades is possible.

The solubility is generally tested after the addition of reducing agents. It is only tested without reducing agents in the case of liquid preparations which are ready for use in dyeing and for thiosulfate esters. For finely dispersed types the fine distribution and the padding liquor stability are also tested. Preparations which are ready for use in dyeing are also standardized in terms of their reducing agent content. Low-sulfide preparations are tested for their total sulfide content.

In analysis for identity comparison, the sulfur dyes contained in the commercial products adjusted to type strength can be readily separated from the additives by dissolving with sodium sulfide in water, precipitation with air, filtering, and washing. Identities can be derived by comparison of the IR spectra of the isolated dyes.

Sulfur dyes cannot be removed from cellulose fibers with reducing agents because of their high substantivity. They can therefore only be detected on textiles as a dye class [12].

8. Storage and Transportation

Commercial products which do not contain any reducing agent are not subject to any specific limitations because of their low toxicity. The safety data sheets of the producer give a dust explosion class for solid commercial products. For transport the dyes are not regarded as dangerous goods. The liquid reduced preparations are subject to the storage and transport regulations of a particular country because of their sulfide content and pH value.

9. Application

Colorations with sulfur dyes predominantly have an average to high fastness level in middle to deep color shades on cellulose fiber. The lightfastness reaches values of almost 8 for black sulfur dyes. The fastness of deep shades to wet rubbing and the resistance to chlorine are problematic. Sulfur dyes are preferably used for economical colorations, e.g., for cord, leisure and outer garments, both on pure cotton and on mixed polyester – cellulose materials. Where deep color shades are to be produced in the colors black, blue, brown, and dark green at favorable prices, the sulfur dyes are without competition.

Table 2. Main producers of sulfur dyes

Producer/country	Range specification	Commercial forms (C.I. classification)
Asahi/Japan	Asathio	sulfur solubilized
	Asathiosol	sulfur
Atul Products/India	Atul Sulphur	sulfur
Cardoner/Spain	Diresul	leuco sulfur
	Pirocard	sulfur
	Pirosol	solubilized sulfur
	Sandozol	solubilized sulfur
Cassella, Hoechst/Germany	Cassulfon	leuco sulfur
	Coranil	solubilized sulfur *
	Hydron	sulfurized vat, dispersed form
	Hydrosol	solubilized sulfur
	Immedial	sulfur
	Imedial C	leuco sulfur
	Indocarbon	sulfur, dispersed form
China National Chemicals/China	Sulphur	sulfur
	Youhaodron	sulfurized vat
Mitsui Toatsu Dyes/Japan	Mitsui Sulphur	sulfur
Nippon Kayaku/Japan	Kayaku	sulfur, dispersed form
	Kayasol Homodye	solubilized sulfur
Patrick/USA	Patcosul	leuco sulfur
Robinson/England	Endurol	sulfurized vat
	Episol	solubilized sulfur *
	Sulphol	sulfur, leuco sulfur
	Sulphosol	solubilized sulfur
Sandoz Chemicals/USA	Sodyeco	sulfur leuco
	Sodyesul	sulfur
	Sodyevat	sulfurized vat, dispersed form
Shanghai Dyestuffs/China	Shangdasulfur	sulfur
Sumitomo/Japan	Nissen	sulfur

* For leather.

Sulfur dyes are used in continuous piece-dyeing works and also on the jigger. In yarn dyeing, in dyeing flocks, dyeing knitwear on winch machines or jet dyeing machines, and dyeing chain yarn for denim articles, black is predominantly used. The dyeing method and the choice of the appropriate commercial form are described in detail in the literature and in the dyeing instructions of the producer [13].

Sulfur dyes are only used in relatively small quantities in other areas. Sulfur Black 1 is used in its various commercial forms in the bulk dyeing of paper, particularly for laminates.

Thiosulfate esters are used in dyeing leather, preferably chrome leather without a reducing agent, and give good colorations throughout with excellent wet- and lightfastness. To improve the absorption of dye the use of special auxiliaries has been proposed [14]. The use of finely dispersed sulfur dyes without reducing agents has been suggested [15].

Other patents describe dyeing the elastomer component of artificial leather [16], dyeing aramid fibers [17], use in ink-jet printing inks [18–21], and the production of pigments for printing inks [22].

Table 2 lists the main producers, trade names, and commercial forms.

10. Economic Aspects

World consumption of sulfur dyes, which depends on cotton consumption and on the color shades that are in fashion, is estimated to be over 100 000 t/a. About 35 % of this is accounted for by North America and Western Europe, and 40 % by the CIS and China. The sulfur dyes account for ca. 30 % of dye consumption for cellulose fibers in terms of quantity, but in terms of value the percentage is much lower. On a long-term average, Sulfur Blacks 1 and 2 account for ca. 65 % of sulfur dye consumption.

11. Toxicology and Occupational Health

The hazard potential of sulfur dyes themselves and on the dyed fiber is regarded as very low because of their macromolecular structures and low bioavailability. Investigations on mammals gave $LD_{50} > 5000$ mg/kg and no skin or mucous membrane irritation. All sulfur dyes investigated gave negative results in the Ames test.

The solid products are now predominantly low in dust.

Reduced preparations are rendered alkaline and contain sodium sulfide, in many cases in the quantity necessary for dyeing. They must be labeled accordingly and may not be brought into contact with acidic substances.

For ecological reasons, low-sulfide reduced preparations are also available, to which additional reducing agents (e.g., glucose) must be added for dyeing.

1. Sulfur – Halogen Compounds

In sulfur halides, sulfur can exhibit the oxidation states 2, 4, or 6. The affinity of sulfur for halogens, and hence the tendency to form higher oxidation states, decreases with increasing atomic radius and decreasing electronegativity of the halogen.

Binary compounds for all typical oxidation states are only known for the sulfur fluorides (see →Fluorine Compounds, Inorganic, Chap. 6.1.→Fluorine Compounds, Inorganic, Chap. 6.2.). Sulfur forms halides of the composition SX_n ($n = 2$, 4, or 6) and S_2X_n ($n = 2$, 4, 10). The halosulfanes S_nX_2 ($n \geq 3$) contain sulfur chains. Besides the binary sulfur halides, the mixed halides SF_5Cl [*13780-57-9*], SF_5Br [*15607-89-3*], and S_2BrCl [*28077-67-0*] are also known.

1.1. Sulfur Chlorides

In the sulfur – chlorine system, the compounds disulfur dichloride (S_2Cl_2), sulfur dichloride (SCl_2), sulfur tetrachloride (SCl_4), and the chlorosulfanes (S_nCl_2, $n \geq 3$) have long been known.

The stability of the sulfur chlorides decreases with increasing oxidation state of the sulfur. Thus, at room temperature S_2Cl_2 can be stored without decomposition, whereas SCl_2 is ca. 16 % dissociated. SCl_4 is only stable at low temperature. Only S_2Cl_2 and SCl_2 have become important industrially.

1.1.1. Disulfur Dichloride

Disulfur dichloride [*10025-67-9*], S_2Cl_2, also known as sulfur monochloride, is the most stable sulfur chloride. It is readily formed on treating sulfur with chlorine at elevated temperature. S_2Cl_2 is an amber liquid with an unpleasant, pungent odor. It fumes in air due to the formation of HCl.

Physical Properties. Some physical properties of S_2Cl_2 are as follows:

Molecular mass	135.03 [6]
Melting point	−82 °C [7]
Boiling point at 0.1 MPa	138 °C
Critical temperature	392 °C [8]
Density at 20 °C	1.6773 g/cm^3 [9]
Dynamic viscosity at 20 °C	0.978 mPa · s [9]
Surface tension, 25 °C	42.5 mN/m [10]
Refractive index n_D^{20}	1.6517 [7]
Dielectric constant, 15 °C	4.79 [11]
Electrical conductivity, 20 °C	$1.3 \times 10^{-10}\ \Omega^{-1}\ cm^{-1}$ [12]
Vapor pressure, 20 °C	1.43 kPa [13]
Specific heat, liquid, 20 °C	0.921 J g^{-1} K^{-1} [14]
Molar heat capacity, gaseous, STP	72.77 J mol^{-1} K^{-1} [15]
Heat of formation	$\Delta H^0_{298} = -58.5$ kJ/mol [16]
Enthalpy of evaporation at 0.1 MPa	36.1 kJ/mol [13]
Ignition temperature	390 °C [17]
Explosion range, 0.1 MPa	4.2 – 32.5 vol % [17]

Chemical Properties. Disulfur dichloride vapors form explosive mixtures with air. On heating, the orange-yellow liquid assumes a reddish tinge due to partial dissociation. On distillation of S_2Cl_2 the vapor phase contains some SCl_2, while the liquid phase becomes enriched in sulfur. Vacuum distillation gives mostly undecomposed disulfur dichloride. S_2Cl_2 acts as a solvent for covalent inorganic and organic compounds such as $SOCl_2$, SO_2Cl_2, $POCl_3$, $AsCl_3$, $TiCl_4$, $COCl_2$, and CCl_4, but does not dissolve saltlike metal compounds. Disulfur dichloride reacts only slowly with water at room temperature. The immiscible liquids form a sulfur film at the phase interface, which inhibits further reaction. On heating, the reaction rate increases explosively. The heat of hydrolysis with excess water is − 146.5 kJ/mol [18].

On hydrolysis elemental sulfur, thiosulfate, polythionic acids $H_2S_nO_6$, HCl, and SO_2 are formed. In the presence of sulfite or SO_2, disulfur dichloride is converted into polythionic acids, elemental sulfur only being formed in trace amounts. S_2Cl_2 reacts with many elements, oxides, and sulfides, with formation of the corresponding chlorides; heating is required in most cases. Titanium reacts vigorously in the cold with incandescence. Because of the formation of protective layers of insoluble chlorides or sulfides, metals such as Ni, Co, Cr, Mn, Cd, Zn, Ag, and Cu are resistant to S_2Cl_2. Disulfur dichloride dissolves large quantities of sulfur, with formation of chlorosulfanes S_xCl_2. Dry ammonia reacts vigorously with S_2Cl_2 to form N_4S_4 [*28950-34-7*]. Depending on the reaction conditions S_7NH, $S_6(NH)_2$, sulfur, and NH_4Cl are formed as side products [19]. S_2Cl_2 is miscible with many organic solvents or is readily soluble in them. Reaction of S_2Cl_2 with organic compounds results in introduction of sulfur, chlorine, or both into the molecule [20–24]. Dehydration and condensation reactions are also known. S_2Cl_2 is an effective catalyst for many chlorination reactions.

With ethylene, S_2Cl_2 forms bis(2-chloroethyl) sulfide [*505-60-2*] (mustard gas) [25]. Reactions of S_2Cl_2 with unsaturated compounds are of industrial interest. Rubberlike products, known as factice, are formed with unsaturated vegetable oils. S_2Cl_2 acts as a cross-linking agent in unsaturated polymers. With aromatic compounds the corresponding mono- or disulfides are generally formed, and also poly(thioarylenes) under certain conditions [26], [27].

Production. Disulfur dichloride is generally produced from the elements. In the batch process, chlorine is passed into a solution of sulfur in S_2Cl_2 with cooling at ca. 50 – 70 °C until the correct chlorine content is reached. In the continuous process, gaseous chlorine is passed into molten sulfur at 220 – 260 °C, and the gaseous S_2Cl_2 leaving the reactor is then condensed [28]. Production is carried out in equipment made of steel or chromium – nickel steel. Disulfur dichloride is an intermediate in the production of CCl_4 and trichloromethylsulfenyl chloride CCl_3SCl [*594-42-3*] from CS_2 and can be obtained from the process as a byproduct. It is also formed in the chlorination of mercaptans to give the corresponding chlorides.

$$2\,RSH + 3\,Cl_2 \longrightarrow 2\,RCl + S_2Cl_2 + 2\,HCl$$

Storage and Transport. S_2Cl_2 is sold in steel or stainless steel drums, tank containers, and tank cars. To avoid corrosion the entry of moisture should be carefully excluded. For handling, see [29].

Transport classification:

IMDG Code	Class 8
UN No.	1828
Packing group	I
RID/ADR	Class 8, no. 21 a
ADNR	Class 8, no. 11 a
ICAP-TI/IATA-DGR	max. 2.5 L

Quality and Analysis. Commercial S_2Cl_2 is a clear liquid, which is light yellow at room temperature and has a chlorine content of 51.5 – 52.5 %. It can contain SCl_2, SO_2, $SOCl_2$, chlorosulfanes, and dissolved sulfur as impurities. The chlorine content is determined by volumetric analysis. The free sulfur and chlorosulfane contents can be determined as the evaporation residue in vacuo (3 hPa). An oily residue indicates the presence of chlorosulfanes. SCl_2, SO_2, $SOCl_2$, and organic impurities are determined by GLC.

Uses. Large quantities of S_2Cl_2 are used in the production of cutting oils and additives for

high-pressure lubricating oils [30]. The S_2Cl_2 is reacted with unsaturated organic compounds, such as olefins, fats, or fatty acids. Since low-chlorine lubricating oils have increased in importance, this use of S_2Cl_2 has declined considerably. By reaction with morpholine or phenols, vulcanizing agents for high-quality rubber grades are obtained [31]. Reaction with vegetable oils gives gel-like substances known as factice, which are used for erasers and as components of rubber compounds. The sulfurization of oils for varnishes is now of very minor importance. Smaller quantities of S_2Cl_2 are used in cold vulcanization of thin-walled rubber articles; for the production of organosulfur compounds, pharmaceuticals, and crop protection agents; and as a chlorination catalyst.

Herz compounds, obtained from S_2Cl_2 and aniline, are important in the production of some sulfur dyes. S_2Cl_2 can also be used as an absorbent for chlorine [32].

Economic Aspects. The consumption of S_2Cl_2 in the Western world was ca. 30 000 t/a in 1987. Of this ca. 85 % was used for the production of lubricant additives, and ca. 2000 t for the production of factice and rubber auxiliaries. Because of the decrease in the consumption of chlorine-containing lubricating agents the annual worldwide S_2Cl_2 consumption decreased to $<$ 15 000 t/a in 1992.

Producers of disulfur dichloride are as follows:

United States:	Occidental Petroleum, Miles
Western Europe:	Bayer, Germany; Elf Atochem and Produit Chimique de Loos, France; Nipa Laboratories, United Kingdom.
Asia:	Transpek, India; Sumitomo Seika, Japan.

Waste. When S_2Cl_2 is used in organic syntheses an off-gas containing HCl, SO_2, H_2S, and S_2Cl_2 is formed. The off-gas can be purified by scrubbing with water, sodium hydroxide solution, or sodium hypochlorite solution in jet washers or packed towers. Residues containing S_2Cl_2 are disposed of in special incinerators.

1.1.2. Sulfur Dichloride

Sulfur dichloride [*10545-99-0*], SCl_2, is an unstable compound which is already ca. 16 % dissociated at room temperature according to the equation:

$$2\,SCl_2 \rightleftharpoons S_2Cl_2 + Cl_2$$

The decomposition can be inhibited be compounds such as PCl_5 or $PSCl_3$.

Physical Properties. Some physical properties of sulfur dichloride are as follows:

Molecular mass	102.97 [6]
Melting point	− 122 °C [7]
Boiling point at 0.1 MPa	59.5 °C [10]
Vapor pressure, 20 °C	21.6 kPa [91]
Density at 20 °C	1.621 g/cm^3 [9]
Surface tension, 25 °C	33.42 mN/m [10]
Viscosity at 20 °C	0.548 mPa · s [10]
Dielectric constant, 15 °C	3.0 [11]
Enthalpy of formation, 25 °C	− 22.2 kJ/mol [33]
Specific heat (liquid, 0 – 140 °C)	1.01 J g^{-1} K^{-1} [10]
Molar heat capacity (gas, 25 °C, 0.1 MPa)	50.89 J mol^{-1} K^{-1} [15]
Explosion range in air, 100 °C, 0.1 MPa	16.3 – 36.5 vol % [34]

Sulfur dichloride is a red liquid which fumes in moist air. It is electrically nonconducting. Although its flash point cannot be determined, it can be ignited in closed vessels when mixed with air. Sulfur dichloride is miscible with many inorganic and organic covalent compounds such as liquid SO_2, S_2Cl_2, $SOCl_2$, SO_2Cl_2, chlorohydrocarbons, and benzene.

Chemical Properties. Sulfur dichloride decomposes rapidly and completely on treatment with water, forming HCl, thiosulfate, and polythionic acids; elemental sulfur is only formed in trace amounts. In its reactions SCl_2 resembles S_2Cl_2. It is a strong chlorinating agent which converts many elements, oxides, and sulfides into chlorides. It forms stable complexes of the type $MCl_2 \cdot SCl_2$ with many metal chlorides. SCl_2 is oxidized to thionyl chloride by oxygen, SO_2, SO_3, or SO_2Cl_2 at elevated temperature, particularly in the presence of catalysts such as activated charcoal [35]. SCl_2 reacts with NH_3 to give S_4N_4, $S_6(NH_2)_2$, and NH_4Cl [36].

Sulfur dichloride generally acts as a strong chlorinating agent towards organic compounds [20]. It readily adds to double bonds [37]. It forms mustard gas on reaction with ethylene. Reactions with organic compounds are described in detail in [20–22], [31], [37–39].

Production. Technical-grade sulfur dichloride is produced by passing gaseous chlorine into S_2Cl_2 at low temperature until the correct chlorine content is reached. Sulfur dichloride can be purified by distillation in the presence of stabilizers [10], [40], [41].

Storage and Transport. The same applies as to S_2Cl_2 (see page 2).

Quality and Analysis. Sulfur dichloride is sold in technical grade with a chlorine content of 66–70 %. The product contains ca. 72–80 % SCl_2, residual S_2Cl_2, and Cl_2. Stabilized pure sulfur dichloride should contain min. 98 % SCl_2. It can only be stored for a limited period.

The analysis is carried out as for S_2Cl_2 by determination of the chlorine content and by GLC.

Waste is treated as for S_2Cl_2 (see page 3).

Uses. As with S_2Cl_2 large quantities of sulfur dichloride are used for the production of lubricating oil additives. Smaller amounts are used in the production of antioxidants, organosulfur compounds, and rubber chemicals.

Economic Aspects. World consumption of technical-grade sulfur dichloride was ca. 8000 t/a in 1992.

Producers:

United States:	Occidental Petroleum
Western Europe:	Elf Atochem and Produit Chimique de Loos, France;
Asia:	Transpek, India; Sumitomo Seika, Japan.

1.1.3. Other Sulfur Chlorides

Sulfur tetrachloride [*13451-08-6*] is a highly unstable compound, which is formed as a fine, white powder on mixing chlorine with SCl_2 below −75 °C [42]. On warming above the melting point of −31 °C it decomposes into SCl_2 and Cl_2.

On cooling S_2Cl_2–Cl_2 mixtures containing 57.2–59.2 atom % Cl_2 to ca. −110 °C a flocculent precipitate is formed which has been referred to as *trisulfur tetrachloride* S_3Cl_4 [43].

Chlorosulfanes (S_xCl_2, $x \geq 3$) [*50864-86-3*] are oily, strongly refractive liquids at room temperature. Their color ranges from light yellow (S_3Cl_2) to orange-red for the higher homologues. The vapor pressure decreases with increasing chain length. The lower chlorosulfanes are formed by treating sulfur with S_2Cl_2. Higher homologues can be obtained by reacting polysulfanes H_2S_x with S_2Cl_2 or by the action of sulfur vapor on S_2Cl_2 at 400–900 °C. Chlorosulfanes with a chain length x of up to 100 have been reported. The analytical identification of the individual homologues can be carried out by using HPLC [44].

1.2. Sulfur Bromides and Iodides

Of the pure sulfur–bromine compounds only disulfur dibromide and the bromosulfanes (S_nBr_2) are known.

Disulfur dibromide [*13172-31-1*], S_2Br_2, is a garnet red liquid. It can be obtained from its constituent elements or by treatment of gaseous HBr with S_2Cl_2 at room temperature [45]. Some physical properties of disulfur dibromide are as follows:

Molecular mass	223.93 [6]
Melting point	−46 °C [46]
Boiling point, 24 Pa	54 °C [45]
Density, 20 °C	2.629 g/cm^3 [47]
Viscosity, 20 °C	2.41 mPa · s [47]
Surface tension, 20 °C	39.1 mN/m [47]
Molar heat capacity (gas, 25 °C)	75.28 J mol^{-1} K^{-1} [48]
Enthalpy of formation (liquid, 25 °C)	−10.5 ± 4.2 kJ/mol [48]

Bromosulfanes (S_nBr_2, $n = 3-8$) are formed quantitatively from chlorosulfanes and HBr at room temperature. They are oily liquids whose colors range from dark red (S_2Br_2) to raspberry red (S_8Br_2) and whose stability decreases as the sulfur chain length increases. Unlike the chlorosulfanes, the density decreases with increasing chain length [47].

Sulfur iodides. Of the sulfur iodides only S_2I_2 [*53280-15-2*] has been detected with certainty so far [49]. It is formed from S_2Cl_2 and I_2 in fluorohydrocarbons at −78 °C [50].

2. Sulfur – Halogen – Oxygen Compounds

Sulfur forms the following types of halogen – oxygen compounds:thionyl halides SOX_2, sulfuryl halides SO_2X_2, and complex sulfur oxyhalides.

The sulfur – halogen – oxygen compounds can be considered formally as derivatives of the sulfur oxyacids in which the OH groups have been replaced by halogens. On hydrolysis with water all S – O – X compounds are converted to the corresponding sulfur acids. Like the sulfur halides the thermal stability decreases with increasing atomic mass of the halogen. Thus SOF_2 and SO_2F_2 are very stable compounds, while $SOCl_2$ and SO_2Cl_2 already dissociate slowly just above the boiling point. $SOBr_2$ can only be distilled in vacuo without decomposing. SOI_2 is only known in solution. Hydrolysis with water shows a similar trend: SO_2F_2 is stable towards hot water, SOF_2 reacts only slowly with water, while $SOCl_2$ or SO_2Cl_2 reacts vigorously and completely with formation of HCl and SO_2, or HCl and H_2SO_4, respectively.

2.1. Thionyl Halides

Thionyl halides are derivatives of sulfurous acid $O{=}S(OH)_2$. The following thionyl halides and mixed thionyl halides are known: SOF_2, $SOCl_2$, $SOBr_2$, SOI_2, SOClF, SOBrF, and SOBrCl. Thionyl chloride has achieved major industrial importance. Thionyl bromide is used as a brominating agent and solvent in preparative organic chemistry. SOI_2 and the other thionyl halides are unsuitable for use in synthesis because of their instability.

2.1.1. Thionyl Chloride

Thionyl chloride [*7719-09-7*], $SOCl_2$, also known as sulfurous oxychloride or sulfinyl chloride, was first prepared in 1849 by treatment of SO_2 with PCl_5 [51], [52]. After it had been obtained pure, its advantages as a reagent, especially as a chlorinating agent, were recognized. From ca. 1900 onwards $SOCl_2$ was sufficiently available and reasonably priced, because of an improved production method, that it could even be used for large-scale industrial syntheses. Thionyl chloride is now one of the most important chlorinating agents in organic chemistry.

Physical Properties. Thionyl chloride is a colorless strongly refractive liquid with a pungent odor. It fumes in moist air due to HCl formation. Unlike $COCl_2$, $SOCl_2$ has a pyramidal structure. Some physical properties are listed below:

Molecular mass	118.97 [6]
Melting point	− 104.5 °C [53]
Boiling point at 0.1 MPa	76 °C [3]
Heat of evaporation at 0.1 MPa	31.3 kJ/mol [54]
Vapor pressure, 20 °C	12.9 kPa [55]
Critical temperature	296.8 °C
Density, 20 °C	1.640 g/cm^3 [56]
50 °C	1.579 g/cm^3 [56]
Surface tension, 18 °C	34.0 mN/m
Viscosity, 25 °C	0.60 mPa · s
Specific heat (liquid)	1.00 J g^{-1} K^{-1} [54]
Molar heat capacity (gas)	66.6 J mol^{-1} K^{-1} [57]
Enthalpy of formation (gas) ΔH^0_{298}	− 244.9 kJ/mol [16]
Refractive index n_D^{20}	1.517 [54]
Dielectric constant, 20 °C	9.05 [54]
Specific electrical conductivity	7 – 60 × 10^{-9} Ω^{-1} cm^{-1} [3]

Chemical Properties. Thionyl chloride is a nonflammable liquid which undergoes slow thermal decomposition on heating above the boiling point:

$$4\,SOCl_2 \longrightarrow S_2Cl_2 + 2\,SO_2 + 3\,Cl_2$$

The decomposition is measurable in the absence of catalysts above 100 °C and is rapid above 180 °C. SO and Cl_2 are probably formed initially [58].

Inorganic salts are generally insoluble in $SOCl_2$, but covalent and organic compounds mostly exhibit good solubility.

Reactions with Inorganic Compounds. Thionyl chloride is hydrolyzed rapidly and completely by water in an exothermic reaction($\Delta H = -136$ kJ/ mol with excess water).

$$SOCl_2 + H_2O \longrightarrow SO_2 + 2\,HCl$$

Thionyl chloride reacts with the water of crystallization of metal chloride hydrates to give the anhydrous metal chlorides.

With many elements $SOCl_2$ forms the corresponding chlorides, SO_2, and S_2Cl_2. The reaction rate varies widely. Some (Sb, Ti) react

vigorously at room temperature, others only on heating. Mg, Zn, Cd, Pb, Cr, and Ni are resistant up to 200 °C. The low reactivity is due to the formation of a protective layer of metal chloride that is insoluble in $SOCl_2$. In the presence of organic compounds, the rate of reaction may increase considerably. $SOCl_2$ generally only reacts with metal oxides at elevated temperature. The oxides of some transition metals (e.g., V, Cr, W) form oxychlorides with $SOCl_2$. The reaction of $SOCl_2$ with silver oxide or silver sulfide Ag_2S at reduced pressure and elevated temperature is used for the synthesis of sulfur suboxide S_2O [59].

$$Ag_2S + SOCl_2 \longrightarrow 2\,AgCl + S_2O$$

Peroxides give the chlorides, sulfates, and sulfuryl chloride. The reaction is sometimes explosive [60].

With some metal chlorides ($AlCl_3$, $ZrCl_4$, UCl_5) $SOCl_2$ forms addition compounds.

Concentrated sulfuric acid reacts with $SOCl_2$ to give chlorosulfonic acid.

$$H_2SO_4 + SOCl_2 \longrightarrow HSO_3Cl + SO_2 + HCl$$

Analogously hydrogensulfates form chlorosulfates. Sulfur trioxide forms pyrosulfuryl chloride $S_2O_5Cl_2$ on reaction with thionyl chloride.

The reaction of $SOCl_2$ with ammonia and other inorganic nitrogen compounds leads to various products, depending on the reaction conditions [19], [61]. Gaseous ammonia reacts exothermically with $SOCl_2$ vapor to give thionyl imide OSNH [*13817-04-4*] and NH_4Cl [62]. The use of thionyl chloride in preparative inorganic and coordination chemistry is described in [63].

Reactions with Organic Compounds. The most important reaction of thionyl chloride is the substitution of OH groups by chlorine in alcohols, carboxylic acids, and sulfonic acids. The reaction is particularly advantageous as the reaction products, SO_2 and HCl, are gaseous and can be removed readily. The reaction proceeds via the intermediate products sulfite and chlorosulfinate:

$$2\,ROH + SOCl_2 \longrightarrow (RO)_2SO + 2\,HCl$$

$$(RO)_2SO + SOCl_2 \longrightarrow 2\,ROSOCl$$

$$ROSOCl \longrightarrow RCl + SO_2$$

Both intermediate products can be isolated. Sulfite formation is favored by low reaction temperature, a large excess of $SOCl_2$, and use of solvents. The decomposition of the chlorosulfinates is catalyzed by tertiary amines. The chlorination of aliphatic OH groups can take place with retention or inversion of configuration, depending on the reaction conditions. In some cases intramolecular rearrangement can occur [54].

The reaction with thiols proceeds similarly:

$$RSH + 2\,SOCl_2 \longrightarrow RCl + S_2Cl_2 + SO_2 + HCl$$

Phenolic OH groups generally do not react. Carboxylic acids are generally converted rapidly by $SOCl_2$ into acid chlorides in good yield. The reaction is accelerated by catalysts such as tertiary amines, carboxylic acid or sulfonic acid amides (e.g., DMF), or inorganic salts (KCl, $ZnCl_2$). However, on using DMF as catalyst, formation of dimethylcarbamoyl chloride, a potential carcinogen, cannot be ruled out. If a large excess of $SOCl_2$ is added to the acid, then the acid anhydride is generally obtained. Thionyl chloride is also important in dehydration and condensation reactions. For reactions in organic chemistry, see [20], [54], [64–66].

Production. Thionyl chloride is now generally produced by treating SO_2 or SO_3 with SCl_2 at ca. 150 – 250 °C in the presence of activated carbon [67], [68].

$$SO_3 + SCl_2 \longrightarrow SOCl_2 + SO_2$$

$$SO_2 + SCl_2 + Cl_2 \longrightarrow 2\,SOCl_2$$

The crude product is purified by distillation after addition of sulfur. Crude thionyl chloride production is a continuous process, but the distillation is carried out either continuously or in batches. The side product SO_2 can be reacted with chlorine to give SO_2Cl_2 and thus recycled.

$$SO_2Cl_2 + SCl_2 \longrightarrow 2\,SOCl_2$$

Older processes [69], which are no longer important, are based on the chlorination of SO_2 with PCl_5 or $COCl_2$

$$SO_2 + PCl_5 \longrightarrow SOCl_2 + POCl_3$$

$$SO_2 + COCl_2 \longrightarrow SOCl_2 + CO_2$$

or the reaction of SCl_2 or S_2Cl_2 with SO_3 or HSO_3Cl.

$$SO_3 + S_2Cl_2 \longrightarrow S + SOCl_2 + SO_2$$

Technical-grade thionyl chloride can contain sulfur chlorides, SO_2, and SO_2Cl_2. Sulfur chlorides can be removed by distillation over sulfur, in some cases with the addition of $FeCl_3$ or $AlCl_3$ [70]. For laboratory-scale purification, distillation with triphenyl phosphite [71] or dipentene [72] is recommended. Modern processes give thionyl chloride in a quality which does not require any additional purification.

Storage and Transport. Thionyl chloride is sold in galvanized steel drums, and in stainless steel railway tank cars and tank containers.

Transport Classification	
IMDG Code	Class 8
UN no.	1836
Packing group	I
RID/ADR	Class 8, no. 21 a
ADNR	Class 8, no. 11 a
ICAP-TI/IATA-DGR	prohibited

Quality Specifications and Analysis. Technical-grade thionyl chloride is a clear, colorless to pale yellow liquid. The thionyl chloride content should be min. 99.6 %. The following impurities can be present: ≤ 0.3 % SO_2, ≤ 0.2 % SO_2Cl_2, ≤ 0.05 % sulfur chlorides, and ≤ 0.1 % evaporation residue.

The IR spectrum can be used for identification. The assay can also be found by determination of the chlorine content. Sulfur chlorides, SO_2, and organic impurities are determined by GLC [73], [74]. Sulfur chlorides can be determined by UV spectrometry, and SO_2 and SO_2Cl_2 by IR spectroscopy [75], [76].

Waste Disposal. In nearly all reactions with thionyl chloride an off-gas is formed which contains predominantly SO_2 and/or HCl, besides thionyl chloride. In addition, varying quantities of organic reactants and solvents can be present. The off-gas stream is generally purified by scrubbing with water or dilute alkali in packed column or jet scrubbers. The resulting wastewater contains chloride and sulfite and must be disposed of according to local regulations. The oxidation of the sulfite to sulfate can be carried out with oxidizing agents, such as chlorine, hypochlorite, or hydrogen peroxide. Oxidation with air or oxygen in the presence of catalysts is also possible. For larger quantitites of off-gas chlorine can be recovered as aqueous hydrochloric acid, and SO_2 as sodium hydrogensulfite solution.

Uses. Thionyl chloride is used in industry for the production of acid chlorides from carboxylic acids, for the production of alkyl chlorides from alcohols, for ester production, and, together with formaldehyde, for chloromethylation.

The production of aromatic sulfonic acid chlorides with chlorosulfonic acid and thionyl chloride is particularly advantageous, as higher yields are achieved compared with the use of chlorosulfonic acid alone and smaller quantities of waste acid are formed [77]. Important areas of use are the production of crop-protection agents, pharmaceuticals, dyes, paper and textile auxiliaries, and plastics.

Smaller quantitites are used as liquid cathodes in certain types of lithium battery [78–80].

Economic Aspects. The annual worldwide thionyl chloride consumption was ca. 45 000 t in 1992.

2.1.2. Thionyl Bromide

Thionyl bromide [*507-16-4*], $SOBr_2$, is an orange-yellow liquid, which becomes red on standing due to decomposition into SO_2, Br_2, and S_2Br_2.

Some physical properties of thionyl bromide are as follows:

Molecular mass	207.85 [6]
Melting point	− 52 °C [53]
Boiling point, 2 kPa	39 °C [81]
0.1 MPa (with dec.)	138 °C [53]
Heat of evaporation, 25 °C, 0.1 MPa	46.1 kJ/mol [81]
Density, 15 °C	2.698 g/cm^3 [53]
Heat of formation (gas) ΔH^0_{298}	− 168.3 kJ/mol [81]
Molar heat capacity (gas)	69.7 J mol^{-1} K^{-} [81]

Chemical Properties. Thionyl bromide is readily soluble in many anhydrous organic solvents, such as CS_2, C_6H_6, or CCl_4, in which it is probably associated. With water complete hydrolysis to SO_2 and HBr occurs immediately. The reactions of $SOBr_2$ with organic compounds are summarized in [54], [82]. It is sometimes used as a brominating agent in preparative chemistry. Carboxylic acids are converted into acyl bromides, and alcohols into alkyl bromides.

Production. Thionyl bromide can be produced by passing HBr into thionyl chloride with cooling and careful exclusion of moisture. For purification the reaction mixture is fractionated under vacuum [45].

2.1.3. Other Thionyl Halides

Thionyl iodide [*55032-43-4*] is formed by the reaction of $SOCl_2$ with HI at $-78\,°C$ in fluorochlorocarbons. The dark brown solid is reported to be stable below $-30\,°C$ [50].

At $0\,°C$ *thionyl chloride fluoride* [*14177-25-4*], SOClF, is a colorless liquid with a choking odor. The boiling point is $12.3\,°C$ and the solidification point $-139.5\,°C$. It is formed by reacting thionyl chloride with IF_5 and condensing the gases produced with liquid air [45]. SOClF is thermally unstable.

Thionyl bromide fluoride [*81539-20-0*], SOBrF, is formed by fluorination of $SOBr_2$ [83]. For thermodynamic data see [84].

Thionyl bromide chloride [*22650-47-1*], SOBrCl, can be detected spectroscopically but cannot be isolated as a pure substance because of disproportionation to $SOCl_2$ and $SOBr_2$. For thermodynamic data, see [84].

2.2. Sulfuryl Halides

Sulfuryl halides are formally derived from sulfuric acid by replacement of both OH groups by halogen. The sulfuryl halides SO_2F_2, SO_2Cl_2, SO_2ClF, and SO_2ClBr are known.

2.2.1. Sulfuryl Chloride

Sulfuryl chloride [*7791-25-5*], SO_2Cl_2, also known as sulfuric oxychloride, is an unstable compound, whose formation in the equilibrium reaction

$$SO_2 + Cl_2 \rightleftharpoons SO_2Cl_2$$

proceeds immeasurably slowly at room temperature in the absence of catalysts.

Physical Properties [1]. Sulfuryl chloride is a colorless liquid with a pungent odor.

Molecular mass	134.97
Melting point	$-54\,°C$
Boiling point, 0.1 MPa	$69.1\,°C$
Heat of evaporation at $69\,°C$	29.6 kJ/mol
Vapor pressure, $18\,°C$	12.7 kPa
Critical temperature	$269-276\,°C$
Density, $25\,°C$	$1.6570\,g/cm^3$
Surface tension, $23.5\,°C$	23.92 mN/m
Viscosity, $25\,°C$	$0.918\,kPa \cdot s$
Specific heat (liquid, $15-63\,°C$)	$0.976\,J\,g^{-1}\,K^{-1}$
Molar heat capacity (gas, $25\,°C$)	$77.5\,J\,mol^{-1}\,K^{-1}$
Enthalpy of formation, $18\,°C$	-389.8 kJ/mol
Refractive index n_D^{20}	1.4437
Dielectric constant, $22\,°C$	9.15
Specific electrical conductivity, $25\,°C$	$3-18 \times 10^{-8}\,\Omega^{-1}\,cm^{-1}$

Chemical Properties. The chemical properties of SO_2Cl_2 are mainly determined by its decomposition into SO_2 and Cl_2. In the absence of catalysts SO_2Cl_2 can be distilled without decomposition. The rate of decomposition is low below $200\,°C$.

SO_2Cl_2 is immiscible with water. The hydrate $SO_2Cl_2 \cdot 15\,H_2O$ is formed with ice-cold water. The strongly exothermic reaction with water, forming sulfuric acid and HCl, is slow at room temperature but becomes explosive at higher temperature or in the presence of catalysts (e.g., I_2). Sulfur dissolves in SO_2Cl_2 without reacting. In the presence of catalysts (e.g., $AlCl_3$) sulfur is chlorinated to S_2Cl_2. Metals generally only react with dry SO_2Cl_2 very slowly at room temperature because of the formation of metal chlorides which are insoluble in SO_2Cl_2. The rate of this reaction is greatly accelerated in the presence of acetonitrile [85]. With ammonia, sulfamide $SO_2(NH_2)_2$ [*7803-58-9*] and imidosulfamide are formed.

Sulfuryl chloride chlorinates, sulfonates, or dehydrates organic compounds. Depending on the reaction conditions and catalysts used the reactions proceed by a radical mechanism (in the presence of peroxides) or by an ionic one (with Lewis acids).

SO_2Cl_2 is particularly suitable for the chlorination of reactive compounds, as it behaves like chlorine of lower reactivity and only forms volatile side products. With tertiary amines SO_2Cl_2 forms stable addition compounds.

Reviews of the reactions of SO_2Cl_2 with organic compounds are given in [86–88].

Production. Sulfuryl chloride is produced almost exclusively by reacting SO_2 and Cl_2 over activated charcoal with cooling [89]. The crude product can then be freed from excess SO_2 or Cl_2 by distillation. Steel or stainless steel are used for the plant equipment, occasionally also lead.

Storage and Transport: as for thionyl chloride (see page 7).

Transport classification:	
IMDG Code	Class 8
UN no.	1834
Packing group	I
RID/ADR	Class 8, no. 21 a
ADNR	Class 8, no. 11 a
ICAP-TI/IATA-DGR	prohibited

In the United States sulfuryl chloride is classed as a material poisonous by inhalation, Zone A. Special regulations apply for packing, labeling, and transport [90].

Quality and Analysis. Technical-grade sulfuryl chloride is a clear, colorless to pale yellow liquid. The sulfuryl chloride content should be min. 99 %; Cl_2 and SO_2 can be present as impurities. The evaporation residue is < 0.01 %. The SO_2Cl_2 content can be found by determining the total chlorine and total sulfur or by GLC.

Waste. In the use of sulfuryl chloride HCl- and/or SO_2- containing off-gas is generally formed, which can be disposed of by scrubbing with alkali. For large quantities of SO_2, recovery as SO_2Cl_2 by reaction with chlorine can be feasible.

Uses. Sulfuryl chloride is mainly used as a mild chlorinating agent, e.g., in the production of chlorophenols or in the side-chain chlorination of aromatics. Other areas of application are the production of sulfonic acids and the sulfochlorination of polyethylene. The use as a liquid cathode in lithium batteries has not become established.

Producers

United States:	Occidental Petroleum

2.2.2. Other Sulfuryl Halides

Sulfuryl chloride fluoride [*13637-84-8*], SO_2ClF, *mp* − 124.7 °C, *bp* 7.1 °C, is a colorless gas that is formed by fluorination of SO_2Cl_2 with SbF_3.

Sulfuryl bromide fluoride [*13536-61-3*], SO_2BrF, *mp* − 86 °C, *bp* 40 °C, is a colorless liquid. It is formed by reaction of SO_2 with BrF_3 and Br_2 [91]. SO_2BrF is quite stable thermally, but is rapidly decomposed by water.

Disulfuryl chloride [*72889-77-1*], pyrosulfuryl chloride, $S_2O_5Cl_2$, is formed by the action of chlorinating agents (S_2Cl_2, $SOCl_2$, PCl_5, CCl_4) on SO_3 or substances that liberate SO_3 [92]. It is a colorless, thermally stable liquid *mp* − 35 °C, *bp* 153 °C, density at 20 °C 1.837 g/cm^3, heat of formation at 18 °C − 697.1 kJ/mol. It decomposes slowly with water, and sulfonates and chlorinates organic compounds. It has not yet achieved any industrial importance.

Polysulfuryl chlorides ($S_nO_{3n-1}Cl_2$) are obtained by reaction of CCl_4 with excess SO_3 with formation of $COCl_2$ as a side product [45], [93].

3. Toxicology

The toxicity of the sulfur halides is based on their hydrolysis, which generates irritant and corrosive substances. The degree of toxicity depends, among other things, on the rate of hydrolytic decomposition. Atmospheric moisture or the moisture of the mucous membranes of the eyes and respiratory tract can be sufficient for this hydrolysis. The results range from irritation of varying degrees to corrosion of the skin, eyes, and respiratory tract. Because of the water solubility of the resulting hydrolysis products, inhalation of the strongly toxic compounds results initially in a so- called upper irritation syndrome as the substances formed dissolve in the

liquid films of the eyes and upper respiratory tract, where they cause irritation or corrosive effects. Inhalation of sufficiently large quantities can cause lung edema because the toxic substances reach the lower respiratory tract after saturation of the liquid film of the upper tract. This severe damage is seldom observed and only when escape from a contaminated atmosphere is impossible (e.g., blocked escape route, unconsciousness). Otherwise the warning action of the irritation of the eyes and upper respiratory tract protects the person from such severe harm. The specific toxic effects arising from inhalation of fluorine or bromine only occur on severe contamination.

Disulfur dichloride, S_2Cl_2, is hydrolyzed by water to give hydrochloric acid, sulfur dioxide, elemental sulfur, and polythionic acids, leading to severe irritation of the eye and respiratory tract. In mice inhalation of 150 ppm (850 mg/m^3) within 1 min is lethal [94]. The LC_{50} (vapor, 4 h) is 441 ppm (2500 mg/m^3) for rats, with an observed NOEL of 32.5 ppm (184 mg/m^3) [95]. The LD_{50} (rat) is 130 mg/kg body weight [95]. Repeated exposure (4 h per day, 25 d) to 0.1 ppm caused effects to the liver and kidneys of rats and rabbits, but not guinea pigs [96]. Corrosive action was detected on the rabbits' ears; even when washed within 30 s, reddening occurred [96]. The hydrolysis product of S_2Cl_2 gave a negative Ames test [95]. In humans 2 – 9 ppm S_2Cl_2 is only moderately irritant [97], but causes inflammation of the mucous membranes of the nose and pharynx [98]. At 10 ppm (56 mg/m^3) symptoms of illness occur after more than a short exposure, and 20 ppm (112 mg/m^3) leads to severely toxic effects within 1 min [99]. After inhalation of high concentrations for 5 h death after 1 d has been reported [94]. The MAK value is 1 ppm or 6 mg/m^3 [100].

Sulfur dichloride, SCl_2, has comparable toxicity to S_2Cl_2 and also liberates HCl. The toxicity of chlorine must also be taken into account (see → Chlorine, Chap. 16.), since SCl_2 is in equilibrium with Cl_2 and S_2Cl_2. The acute LD_{50} (rat) is 293 mg/kg body weight (not stabilized) and 343 mg/kg body weight (stabilized) [101].

Chlorosulfonic acid, $HOSO_2Cl$, is hydrolyzed to hydrochloric and sulfuric acid and therefore has a strongly corrosive and irritant effect on the mucous membranes and skin [102]. The LC_{50} (rat, 4 h) is 38.5 mg/m^3 (mouse, 2 h: 25 mg/m^3). In these animals general toxic effects occur in the range 8.1 – 10.4 mg/m^3 [103].

Thionyl chloride, SO_2Cl, hydrolyzes rapidly with water and atmospheric moisture giving HCl and SO_2. The LC_{50} (rat, 4 h) is 2700 mg/m^3 with an NOEL of 5 mg/m^3, and the LC_{50} (rat, 1 h) is 6200 mg/m^3 [104] or ca. 2500 mg/m^3 [105]. Thionyl chloride is highly irritant/corrosive to the respiratory tract, eyes, and skin [106]. It gives varying results in the Ames test [106]. In humans severely toxic effects occur on more than a short exposure to 10 ppm (50 mg/m^3), and at 20 ppm (100 mg/m^3) within 1 min [99]. Death due to lung edema after 6 min exposure to a calculated maximum of 17 000 ppm SO_2 has been reported [107].

Sulfuryl chloride, SO_2Cl_2, reacts slowly with water at room temperature and vigorously on heating, giving HCl and H_2SO_4. The latter can give rise to severe local irritant and corrosive effects. At higher temperature an equilibrium involving SO_2 and Cl_2 is established, so their toxicity must also be considered (see → Chlorine, Chap. 16.; → Sulfur Dioxide). The LC_{50} (rat, 4 h) is 159 ppm (873 mg/m^3) [108]. Repeated exposure (rat, 2 weeks, 5 d per week, 6 h per day) with 30 ppm (165 mg/m^3), reduced to 20 ppm (110 mg/m^3) after 2 days, led, after 8 d of exposure, to the death of 2 animals; with 10 ppm (55 mg/m^3) an increase in the hemoglobin and red blood cell count, the lung/body weight quotient, and fibrinous-necrotic bronchopneumonia were observed [108]. Sulfuryl chloride is corrosive to the skin [109]. One strain gave a positive result without metabolic activation in the Ames test and three strains were negative [104]. In humans 4 ppm (22 mg/m^3) can lead to symptoms of illness on more than short exposure, and 10 ppm (55 mg/m^3) causes severe toxic effects [99]. A case of lung edema has been reported for sulfuryl chloride [110].

Thionyl bromide, $SOBr_2$, also undergoes hydrolysis with an irritant effect. In humans general symptoms were observed such as somnolence, nausea, and headaches, and increased bronchovascular markings of the lung in X-ray photographs [111], [112]. Symptoms of bromine poisoning should also be taken into account (see → Bromine, Chap. 9.).

Based on the corresponding article in Ullmann, 4th ed., written by ULRICH SANDER, ULRICH ROTHE, and ROLF KOLA (English Edition: British Sulphur Corporation, 1984)

1. Introduction

Of all the heavy industrial chemicals, sulfuric acid is perhaps the most fundamentally important, in that it has a number of large-scale uses not only within the chemical industry but in other industries as well. By far the most important user is the phosphate fertilizer industry. Other important applications of sulfuric acid are found in petroleum refining, pigment production, steel pickling, nonferrous metals extraction, and the manufacture of explosives, detergents, plastics, and man-made fibers. Many specialty areas of the chemical industry also use varying amounts of sulfuric acid including the production of dyes, pharmaceuticals, and fluorine chemicals.

The consumption of sulfuric acid has many times been cited as an indicator of the general state of a nation's economy, and although many other indicators (such as energy consumption)

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a25_635

might today be regarded as more important, sulfuric acid consumption still follows general economic trends. For example, the recession that resulted from the "energy crisis" of 1974 was clearly reflected in the pattern of sulfuric acid consumption in the following three years. The recession a few years later was similarly accompanied by a generally declining trend in sulfuric acid consumption starting in mid-1980.

Sulfuric acid is manufactured from sulfur dioxide. The primary raw material for producing this intermediate is elemental sulfur (→ Sulfur ; → Sulfur Dioxide). A large involuntary producer of sulfur dioxide is the nonferrous metals industry, the roasting and smelting processes of which generate off-gases with a sufficiently high concentration of sulfur dioxide to permit direct processing to sulfuric acid as a by-product (→ Sulfur Dioxide, Chap. 5.5.).

A significant number of sulfuric acid facilities have been installed in metallurgical plants for the recovery of SO_2, mainly for environmental reasons. To an increasing extent the acid produced in such plants is replacing acid formerly obtained from elemental sulfur (or pyrite). An important task for the years ahead is to establish an infrastructure for distributing this "metallurgical acid" to consumers, especially in the fertilizer industry.

Pyrite still serves in several countries as a raw material for sulfuric acid production, but production rates are no longer significant compared to the other sources described.

Sulfur dioxide is also produced in the thermal decomposition stage of sulfuric acid regeneration from the heavily contaminated sulfuric acid ("spent acid") created by certain industrial processes in which sulfuric acid is introduced(→Sulfur Dioxide, Chap. 5.6.1.). A further source of sulfur dioxide for sulfuric acid production is the combustion of waste gases containing hydrogen sulfide (→ Sulfur Dioxide, Chap. 5.7.).

In theory, there is enough sulfur dioxide to supply all the world's sulfuric acid needs in exhaust gases released during the combustion of sulfur-containing coal, fuel oil, and other fossil fuels in power stations and large industrial boilers. Although it is possible to recover such SO_2 in a concentrated form by regenerative flue-gas desulfurization processes, or to convert it directly into H_2SO_4, only a minor amount of sulfuric acid is prepared by this route. Numerous flue-gas desulfurization plants installed recently as a way of complying with environmental regulations instead convert the SO_2 into gypsum, primarily for economic reasons. Unless environmental regulations require desulfurization of combustion gases, flue-gas sulfur dioxide is simply discharged into the atmosphere – where, ironically, it is then transformed by atmospheric processes into sulfuric acid, which ultimately returns to earth dissolved in rainfall.

Essentially all sulfuric acid today is manufactured by the contact process. The corresponding technology is very mature, although important alterations in the detailed arrangement of the conversion and absorption stages were introduced commercially in the 1960s to increase the sulfur dioxide conversion efficiency, primarily in the interest of environmental protection. Some plants are now designed for a sulfur dioxide conversion efficiency exceeding 99.8 %. Nevertheless, the basic principle of the process remains the same today as when it was first introduced in the 1930s.

Modern plants can be designed to be extremely efficient in terms not only of sulfur dioxide conversion but also energy recovery. It has been common practice for many years to recover 60 % or more of the total energy released in sulfuric acid production in the form of high-pressure steam. The energy efficiency of some plants has recently been very substantially increased, however, by providing for additional recovery of low-level heat from the acid system.

In the attempt to comply with requirements for existing metallurgical complexes, sulfuric acid plants have been developed and constructed for treating gases containing as little as 2 % SO_2 (in a single-catalysis plant; 5 % in a double-catalysis plant – see Section 4.1.4). A current objective is to process sulfur dioxide gas streams with the highest SO_2 concentrations possible in the interest of reducing capital and operating costs and increasing further the extent of high-temperature energy recovery. At the same time, quality requirements have become more strict for commercial acid. Given the large quantities of "metallurgical acid" now entering the market it will be necessary to develop new processes for eliminating such impurities as may still be present.

Yet another important challenge facing sulfuric acid makers is the reprocessing of acid wastes from user industries. It is a peculiarity of sulfuric acid that very little of the material actually ends up in the products it is used to make. Indeed, apart from small-volume products such as pharmaceuticals, almost the only end products with sulfur values comparable to sulfuric acid are synthetic detergents – and even they are ultimately destined for the drain. Many uses result in so-called *spent acid:* sulfuric acid in varying states of dilution as well as contamination with organic and inorganic impurities. Environmental authorities are becoming increasingly intolerant of the sometimes rather casual waste-disposal methods of the past, and the industry is under pressure to accept greater amounts of used acid for reconcentration, purification, or regeneration. Although the technology in this field is already quite extensive (see Section 4.3), further development can be expected in the use of recovered heat from sulfuric acid plants.

2. Properties

2.1. Physical Properties

Pure sulfuric acid [*7664-93-9*], H_2SO_4, M_r 98.08, is a colorless, water-white, slightly viscous liquid, *mp* 10.4 °C, *bp* 279.6 °C, and d_4^{15} 1.8356. It can be mixed with water in any ratio. Aqueous sulfuric acid solutions are defined by their H_2SO_4 content in weight-percent terms. Anhydrous (100 %) sulfuric acid is even today sometimes referred to as "monohydrate," which simply means that it is the monohydrate of sulfur trioxide. Sulfuric acid will dissolve any quantity of SO_3, forming oleum ("fuming sulfuric acid"). The concentration of oleum is expressed in weight-percent of dissolved SO_3 ("free SO_3") in 100 % H_2SO_4.

The physical properties of sulfuric acid and oleum [1–3] are dependent on the H_2SO_4 and SO_3 concentrations, the temperature, and the pressure. Figure 1 shows the *densities* of sulfuric acid and oleum as a function of temperature and concentration [4]. At constant temperature, the density of sulfuric acid increases steeply with rising H_2SO_4 concentration, reaching a maximum at about 98 %. From there up to a concentration of 100 % the density decreases slightly, but it rises again in the oleum range up to a concentration of ca. 60 % free SO_3.

Figure 1. Oleum and sulfuric acid density as a function of temperature and concentration [4]

On account of the clear relationship between density and concentration at defined temperatures in the lower concentration range, density measurement provides a quick method for determining concentration up to about 95 % H_2SO_4.

Hydrometers used for this purpose were formerly calibrated in "degrees Baumé" (°Bé), and for that reason sulfuric acid concentration was often, and sometimes still is, expressed in °Bé. The density ρ in g/cm^3 is given by the expressions

$$r = 144.3/\left(144.3 - {}^{\circ}\mathrm{B}\right)^{[d12]}_{e} \text{ (Europe)}$$

$$r = 145/\left(145 - {}^{\circ}\mathrm{B}\right)^{[d12]}_{e} \text{ (United States)}$$

The *electrical conductivity* of sulfuric acid at 20 °C as a function of concentration is shown in Figure 2 (see next page). The peculiar shape of the curve is due to the various states of ionic dissociation present in the system $H_2O/H_2SO_4/SO_3$ at different concentrations. Conductivity measurement is thus also

Figure 2. Electrical conductivity of sulfuric acid and oleum at 20°C

Figure 3. Dynamic viscosity of sulfuric acid [5]
a) At 25°C; b) At 45°C; c) At 60°C; d) At 80°C

useful as a method for determining the concentration of sulfuric acid.

The *dynamic viscosity* of sulfuric acid as a function of concentration at various temperatures is shown in Figure 3 [5].

The various maxima and minima observed on the *freezing point* curve of sulfuric acid and oleum, shown in Figure 4 [6], are due to the existence of different sulfuric acid hydrates at different temperatures. Whereas the 98.0 – 98.5 % acid used for sulfur trioxide absorption in sulfuric acid production (Section 4.1.3) solidifies at about − 1 to + 1 °C, commercial 96 % sulfuric acid (66°Bé) solidifies at ca. − 15 °C. Commercial 66°Bé acid in the United States contains only 93.2 wt % H_2SO_4 and has a freezing point of ca. − 29 °C. This behavior is obviously of importance if sulfuric acid is to be stored or transported under very cold conditions.

Figure 5 is a phase diagram for aqueous solutions of sulfuric acid based on boiling point measurements by Haase and Rehse [7]. The

Figure 4. Freezing point curve for sulfuric acid and oleum [6]

Figure 5. Boiling curves for sulfuric acid at 1013 mbar [7]
a) Vapor; b) Liquid

lower curve shows the relationship between the boiling point of sulfuric acid and its concentration, while the upper curve shows the sulfuric acid concentration in vapor evolved from acid boiling at a particular temperature. When an aqueous solution of sulfuric acid is boiled, the vapor contains more water than the boiling acid, so the concentration of the acid in-

creases and its boiling point rises. This continues until the boiling point reaches a maximum of ca. 339 °C at a sulfuric acid concentration of 98.3 wt % H_2SO_4. At this point the liquid and vapor phases are identical in composition, corresponding to an azeotrope, so the concentration of the boiling acid cannot increase further. As can be seen from Figure 5, if vapor in equilibrium with sulfuric acid of 85 wt %, boiling at about 223 °C, is completely condensed it will contain about 7 wt % H_2SO_4. At concentrations below ca. 75 wt % H_2SO_4, essentially nothing but water evaporates. The boiling behavior of sulfuric acid is especially important with respect to industrial processes for thermal concentration of dilute acid. As noted above, the azeotropic concentration (98.3 wt % H_2SO_4) represents the ultimate limiting concentration that can be reached by this method.

The vapor above concentrated sulfuric acid containing more than 98.3 wt % H_2SO_4 includes not only a greater proportion of H_2SO_4 than the liquid but also considerable quantities of SO_3. The vapor over oleum consists almost entirely of SO_3. Figure 6 shows the equilibrium vapor pressures of H_2O, H_2SO_4, and SO_3 above sulfuric acid at 60 °C in the concentration range from 85 wt % H_2SO_4 to 15 % SO_3 oleum, based on measurements made by Lucinskij [8]. These vapor-pressure curves are all-important in gas drying and SO_3 absorption, essential steps in the production of concentrated sulfuric acid by the contact process (Section 4.1.3).

Apart from the field of sulfuric acid manufacture, the system $H_2O/SO_3/H_2SO_4$ is also of immense importance in connection with the combustion of sulfur-containing fuels. It is essential to ensure that the temperature of the combustion gas does not drop below the dewpoint [9, 10] prior to discharge, since otherwise there is a danger of corrosion by condensing sulfuric acid. Various formulae have been developed [11–13] for calculating dewpoints theoretically as a function of the total gas pressure as well as the H_2O, SO_3, and H_2SO_4 partial pressures [14]. Unfortunately, the situation is further complicated by the possible formation of various types of hydrated and associated molecules in the gas phase [15].

The *specific heat* of sulfuric acid falls as concentration increases. Figure 7 shows the dependence of specific heat on concentration and temperature [4]. The *standard enthalpy of formation* for pure liquid H_2SO_4 is − 8.305 kJ/kg, and the *latent heat of evaporation* at the boiling point is ca. 605 kJ/kg [16]. Figure 8 (see next page) shows the enthalpies of liquid sulfuric acid and oleum over a wide concentration range at temperatures between 0 °C and the boiling point [17], assuming an arbitrary value of 0 kJ/kg as the enthalpy of pure water at 0 °C. This diagram

Figure 6. Equilibrium vapor pressures over sulfuric acid and oleum [8]

Figure 7. Specific heat of sulfuric acid [4]

Figure 8. Enthalpy diagram for sulfuric acid and oleum [17]

provides a simple method for determining the amount of heat liberated when sulfuric acid or oleum is diluted from one concentration to another by addition of water.

The amount of heat produced by diluting concentrated sulfuric acid with water is considerable, so rapid mixing is important to ensure that local overheating and boiling are avoided. If one wishes to concentrate dilute acid, a corresponding amount of heat, the so-called *heat of dehydration*, must be supplied in addition to such heat as may be required to evaporate the water. Figure 9, which has been calculated from enthalpy values, shows the heat of hydration evolved in the dilution of 98.3 % acid to lower concentrations at 20 °C (or, conversely, the amount of heat theoretically required to dehydrate it from lower concentrations up to 98.3 %). The heat of hydration liberated by diluting between intermediate concentrations – from 75 % H_2SO_4 to 25 %, for example – is simply the difference between values read off the curve opposite the appropriate concentrations.

2.2. Chemical Properties

Sulfuric acid is a strong acid with characteristic hygroscopic and oxidizing properties. Sulfuric acid, like the sulfate ion, is chemically and

Figure 9. Heat of dilution or dehydration of sulfuric acid at 20°C

thermally very stable. The dehydrating effect of concentrated sulfuric acid is due to the formation of hydrates. Several hydrates have been identified in the solid state, and these explain the irregular variation of some of the physical properties of sulfuric acid with concentration, such as its freezing temperature (see Fig. 4). Known hydrates are $H_2SO_4 \cdot H_2O$ (corresponding to 84.5 wt % H_2SO_4); $H_2SO_4 \cdot 2\,H_2O$ (71.3 wt % H_2SO_4); $H_2SO_4 \cdot 3\,H_2O$ (64.5 wt % H_2SO_4); $H_2SO_4 \cdot 4\,H_2O$ (57.6 wt % H_2SO_4); and $H_2SO_4 \cdot 6\,H_2O$ (47.6 wt % H_2SO_4) [1].

Pure sulfuric acid is ionized to only a small extent as expressed by Equations (1) and (2) [1].

$$2\,H_2SO_4 \rightleftharpoons H_3SO_4^+ + HSO_4^- \quad (1)$$

$$2\,H_2SO_4 \rightleftharpoons H_3O^+ + HS_2O_7^- \quad (2)$$

This is the reason why the electrical conductivity of a sulfuric acid solution has its lowest value at 100 % H_2SO_4 (see Fig. 2). When pure sulfuric acid is diluted with water, dissociation occurs increasingly according to Equation (3).

$$H_2SO_4 + H_2O \rightleftharpoons H_3O^+ + HSO_4^- \quad (3)$$

The conductivity rises accordingly. Between 92 wt % and 84.5 wt % H_2SO_4, the monohydrate ($H_2SO_4 \cdot H_2O$) exists preferentially in equilibrium with the ionic species, so the conductivity decreases slightly. At lower H_2SO_4 concentrations the extent of dissociation increases, as does therefore the conductivity.

At high water content the second stage of dissociation becomes increasingly immportant (Eq. 4).

$$HSO_4^- + H_2O \rightleftharpoons H_3O^+ + SO_4^{2-} \quad (4)$$

On account of the diminishing total concentration of sulfuric acid, however, the conductivity reaches a maximum at ca. 30 wt % H_2SO_4 (the exact value depends on the temperature), and decreases steeply down to 0 wt % H_2SO_4 [1]. Dilute sulfuric acid is the preferred electrolyte for industrial metal electrowinning and electroplating plants on account of its high conductivity and the chemical stability of the sulfate ion. To take advantage of the electrical conductivity maximum, sulfuric acid of about 33 % concentration is used in lead storage batteries (→ Batteries, Chap. 4.).

Dilute sulfuric acid is a strong dibasic acid, so it will dissolve all base metals. Hydrogen is released, and the respective metal sulfates and bisulfates (hydrogensulfates) are formed. Barium and lead are exceptions, not because they do not react in the first place but because they become coated with an insoluble sulfate layer that protects them from further attack by the acid [1]. Hot, concentrated sulfuric acid has an oxidizing effect, reacting with precious metals and with carbon, phosphorus, and sulfur, by which it is reduced to sulfur dioxide.

A very important property of sulfuric acid is its ability to decompose the salts of most other acids. Examples of industrial importance include:

1) Production of sodium sulfate and hydrogen chloride from sodium chloride (→ Hydrochloric Acid, Chap. 3.1.; → Sodium Sulfates, Chap. 1.3.4.)
2) Decomposition of sulfites to sulfur dioxide
3) Decomposition of phosphate rock (natural calcium phosphates) to phosphoric acid and calcium sulfate (→ Phosphoric Acid and Phosphates, Chap. 1.2.2.).

The reactions of concentrated sulfuric acid with organic compounds are frequently dominated by its oxidizing and hygroscopic properties [1]. Carbohydrates, for example, are decomposed to the point of carbonization. Organic condensation reactions in which water is eliminated are promoted by sulfuric acid because it effectively removes the water as soon as it is formed. Sulfuric acid is therefore frequently used in industry for this purpose. It also exercises a catalytic effect on certain reactions involving organic compounds.

Sulfuric acid is thermally extremely stable. Only at very high temperatures is it partially decomposed into its anhydride, sulfur trioxide, and water vapor (Eq. 5).

$$H_2SO_4 \rightleftharpoons SO_3 + H_2O \tag{5}$$

The reverse of this reaction is the overall route by which sulfuric acid is formed in the absorption section of a contact sulfuric acid plant. However, it is not possible in practice to manu-facture sulfuric acid by absorbing sulfur trioxide directly into water, because the sulfur trioxide reacts with water vapor in equilibrium with the liquid near the surface, initially forming sulfuric acid vapor. This quickly condenses as a mist of very fine (submicron) droplets, which are practically impossible to collect. However, sulfuric acid itself reacts readily with sulfur trioxide to form disulfuric acid (Eq. 6), which can be converted back to sulfuric acid by reaction with water (Eq. 7).

$$H_2SO_4 + SO_3 \rightleftharpoons H_2S_2O_7 \tag{6}$$

$$H_2S_2O_7 + H_2O \rightleftharpoons 2\,H_2SO_4 \tag{7}$$

It is therefore quite feasible to absorb sulfur trioxide in sulfuric acid of 98 % or higher concentration, over which the partial pressure of water vapor is very low, thus avoiding the problem of mist. However, because the vapor pressures of both H_2SO_4 and SO_3 increase steeply at concentrations above 99 % H_2SO_4, the optimum sulfur trioxide absorption efficiency is achieved in 98 – 99 % acid.

If sulfur trioxide is produced in a gas stream that already contains moisture, gaseous sulfuric acid forms progressively by reaction (5), the thermodynamic equilibrium point of which is shifted towards H_2SO_4 with decreasing temperature [18]. The resulting sulfuric acid can then be condensed in a controlled manner without significant mist production. This route to sulfuric acid is also exploited in industry.

The vapor pressure of sulfur trioxide over oleum or disulfuric acid is appreciable, so when oleum is exposed to ambient air, which always contains moisture, sulfuric acid mists invariably form. It is this property that gives oleum its familiar name of fuming sulfuric acid.

Pure disulfuric acid, $H_2S_2O_7$, which corresponds theoretically to oleum with 44.9 wt % free SO_3, crystallizes at ca. 35 °C, the maximum of the freezing-point curve in the oleum range

(see Fig. 4). Disulfuric acid is partially dissociated in sulfuric acid solution (Eq. 8).

$$H_2S_2O_7 + H_2SO_4 \rightleftharpoons H_3SO_4^+ + HS_2O_7^- \quad (8)$$

It is for this reason that the electrical conductivity of oleum rises slightly as the SO_3 concentration is increased from 0 to about 10 wt % free SO_3.

Sulfuric acid is oxidized both by hydrogen peroxide and anodically to diperoxysulfuric acid, $H_2S_2O_8$, and the unstable monoperoxysulfuric acid (Caro's acid), H_2SO_5 (Eq. 9).

$$H_2O_2 + H_2SO_4 \rightleftharpoons H_2SO_5 + H_2O \quad (9)$$

Since it is a strong oxidant, Caro's acid can oxidize sulfur dioxide to sulfuric acid, a property that has been exploited in pollution control for sulfuric acid plants (the Peracidox process, Section 4.1.5).

Nitrogen oxides ($NO + NO_2$) react with sulfuric acid at concentrations above 70 wt % H_2SO_4 to give nitrosyl hydrogensulfate, $NOHSO_4$ (see Section 4.2).

3. Development of the Sulfuric Acid Industry

Detailed descriptions of the development of sulfuric acid production procedures can be found in the literature [19–23].

3.1. Early Development

In the late Middle Ages, sulfuric acid was obtained in small quantities in glass vessels in which sulfur was burned with saltpeter in a moist atmosphere. Higher rates of production first became possible with the introduction of *lead chambers* as reaction vessels by Roebuck, in Birmingham, England, in 1746. The next major step forward came in 1793, when Clement and Desormes achieved better results by introducing supplemental air into the lead chamber process. They interpreted this as meaning that the nitrous gases were acting only as facilitators of the process, and that the oxidation itself was being effected by the air (i.e., oxygen).

In 1827, Gay-Lussac introduced a method for absorbing nitrogen oxides from the lead-chamber off-gases. With the further development by Glover in 1859 of a method for recovering nitrogen oxides from the newly formed acid by stripping with incoming hot gases, it became possible to make the nitrogen oxide-catalyzed process continuous.

As early as 1831, Phillips, in Bristol, England, had patented the oxidation of sulfur dioxide to sulfur trioxide over a platinum catalyst at high temperature. Nevertheless, it was only after oleum demand for dye manufacture began to increase – from about 1872 onward – that this invention was adopted by industry, and intensive development of the *contact process* began. Better solid catalysts were then sought, and the chemistry and thermodynamics of the SO_2/SO_3 equilibrium were investigated. Systematic studies undertaken by Knietsch at BASF on the reaction equilibrium of SO_2 oxidation over a platinum catalyst, published in 1901 [24], formed an important basis for an understanding of thermodynamic principles.

3.2. Further Development of the Nitrogen Oxide Process

The growth in popularity of the contact process stimulated new competitive efforts to improve the lead chamber process. The most significant development was replacement of the lead chambers themselves with acid-irrigated towers, which substantially reduced the specific space requirements. The first so-called tower plant was built by Opl in 1907. However, widespread industrial use of the tower process had to await the development of adequate acid pumps. In 1923, Petersen introduced an improved tower process that remaine competitive with the contact process up to the 1950s. However, a fundamental disadvantage of the nitrogen oxide processes is that product concentration is limited to a maximum of 70 – 75 %, while the contact process produces concentrated (98 %) acid. With the development of relatively inexpensive vanadium catalysts for the contact process together with increasing demand for concentrated sulfuric acid, the proportionate share of world sulfuric acid output produced in nitrogen oxide process plants declined steadily. Around 1910, these accounted

for ca. 80 % of production in Western Europe and North America. By 1930 the figure had shrunk to about 73 %, by 1950 to 20 – 25 %, and by 1960 to ca. 15 % [23]; in 1980 virtually no acid was being produced in nitrogen oxide process plants in these parts of the world. Nonetheless, the nitrogen oxide process has continued to be the object of interest and a certain amount of development work, especially for the processing of gases with extremely low SO_2 content (see Section 4.2).

3.3. Ascendency of the Contact Process

Platinum remained the predominant catalyst for the contact process until the 1930s. As early as 1913, however, BASF was granted a patent [25] for a catalyst based on vanadium pentoxide, which eventually succeeded in replacing the platinum catalyst because of its insensitivity to catalyst poisons and its considerably lower cost.

In 1936/37 Lurgi introduced the wet contact process for converting moist sulfur dioxide-containing gases over a vanadium catalyst. This made it possible to process hot gases from the combustion of hydrogen sulfide in coking plants directly to sulfuric acid.

In succeeding years a number of factors affected the development of the contact process. First, the raw material basis of the industry changed progressively from mainly roaster gases to sulfur combustion gases containing higher concentrations of sulfur dioxide. Second, plant capacities increased as a result of a great rise in the consumption of sulfuric acid by the fertilizer industry. These and other factors provided a stimulus for the introduction of improvements in the individual process steps and in the design of associated equipment (e.g., the shift to tray converters from tube converters).

Double Absorption. In 1960, a patent application was filed by Bayer [26] for the so-called double-catalysis process, and the first plant using this process, built by Lurgi, started up in 1964 [27]. By incorporating a preliminary SO_3 absorption step ahead of the final catalytic stages, the improved contact process permitted a decisive increase in overall SO_2 conversion, thus reducing SO_2 emissions substantially. Because the essential difference between this process and the ordinary contact process is in the number of absorption stages, itis referred to hereafter as the "double-absorption" process.

Environment and Energy. In the 1970s the principal industrial countries introduced more stringent regulations for environmental protection, which made the use of the double-absorption process more or less mandatory in new plants. Nevertheless, the conventional contact process continues to be used in countries where environmental regulations are less exacting.

On account of the steep rise in energy costs, the main thrust of current development in the contact process is toward increasing the recovery and utilization of the very substantial amount of process heat. Indeed, a large, modern sulfuric acid plant may be looked upon not just as a chemical plant but also as a thermal power plant [28–32].

3.4. Raw Materials Usage

The principal starting material for sulfuric acid production is sulfur dioxide, which can be obtained by different methods from various raw materials (→ Sulfur Dioxide, Chap. 3.). Moderately concentrated sulfuric acid is also produced by reconcentration and purification of so-called spent or waste sulfuric acid. Reprocessing spent acids, which are generated in large quantities in many processes, and recycling the regenerated acid to the user is becoming increasingly important from an environmental protection standpoint especially in the major industrial countries [33].

Up about 1970, pyrite was the predominant raw material, maintaining a 57 – 62 % share of the continually rising total. Thus, in 1962, out of a total of ca. 3.1×10^6 t of sulfuric acid, about 1.9×10^6 t (62 %) was made from pyrite; in 1970, about 2.7×10^6 t was pyrite-based, corresponding to ca. 61 % of the total production of ca. 4.4×10^6 t [34]. Since 1970, the proportionate role of pyrite has been declining relative to the total, which has continued to rise. In 1979, pyrite accounted for only ca. 24 %.

Since the beginning of the 1970s, production of sulfuric acid from elemental sulfur in the Federal Republic of Germany has grown faster than total acid production, in step with rapid growth

in the production of recovered sulfur from the refining of crude oil or purification of natural gas from the gas fields of Northern Germany. The proportion of total sulfuric acid production derived from elemental sulfur increased from ca. 30 % in 1970 to ca. 50 % in 1979, when total production stood at about 5×10^6 t [34].

Sulfuric acid manufacture based on elemental sulfur and pyrite is, of course, relatively sensitive to market conditions, because acid produced from these materials represents a primary product. The same is not true of sulfuric acid production based on any of the other sulfur-containing raw materials. In those cases, sulfuric acid is a secondary product, manufactured as a means of disposing of waste from another process. The level of production is therefore dictated not by conditions in the sulfuric acid market, but by conditions in the market for the primary product. Typical sources of this so-called fatal acid are sulfuric acid plants associated with nonferrous metal smelters processing sulfide ores. The quantity of fatal acid produced in the Federal Republic of Germany has been rising constantly, reaching ca. 1.3×10^6 t in 1979 (ca. 26 % of the total).

The raw material basis for sulfuric acid production in other European countries has followed a pattern generally similar to that in the Federal Republic of Germany. Pyrite remained the dominant raw material until the 1950s, and it was only with the advent of large quantities of recovered sulfur from the Lacq natural gas fields in France, and later from natural gas operations in Canada, that elemental sulfur assumed its current predominance.

In contrast, the United States industry has been based since the early years of this century on elemental sulfur because of development of the Frasch industry in the Gulf states (→ Sulfur, Chap. 5.5.). In 1978, the various raw materials accounted for the following approximate proportions of the total U.S. sulfuric acid production of ca. 36×10^6 t [35] in 1963 and of ca. $280\text{x}10^6$ t in 1993:

Elemental sulfur	79 %
Nonferrous sulfide ores	9 %
Waste acid	5 %
Pyrite and hydrogen sulfide	3 %
Miscellaneous	4 %

4. Production

4.1. Production by Contact Processes

4.1.1. Reaction Kinetics and Thermodynamics

In the contact process, a gas mixture containing sulfur dioxide is passed together with oxygen over a catalyst to oxidize the sulfur dioxide to sulfur trioxide (Eq. 10) [36]:

$$SO_2 + 1/2\,O_2 \rightleftharpoons SO_3 \quad \Delta H^\circ = -99.0\,\text{kJ} \tag{10}$$

The sulfur trioxide is then absorbed in sulfuric acid where it reacts with added water to form more sulfuric acid (Eq. 11).

$$SO_3\,(g) + H_2O\,(l) \rightleftharpoons H_2SO_4\,(l) \quad \Delta H^\circ = -132.5\,\text{kJ} \tag{11}$$

The position of equilibrium in the gas-phase exothermic oxidation of sulfur dioxide to sulfur trioxide (Eq. 10) depends on the prevailing temperature, total pressure, and concentrations (partial pressures) of the reactants. Thermodynamic equilibrium is determined by the equilibrium constant K_p according to the law of mass action:4

$$K_p = \frac{p\,(SO_3)}{p\,(SO_2)\cdot p\,(O_2)^{0.5}}$$

On account of the negative reaction enthalpy of sulfur dioxide oxidation, both K_p and the SO_2 equilibrium conversion decrease with rising temperature. The classical relationship between K_p (in atm $^{-0.5}$) and temperature was developed empirically by Bodenstein and Pohl [37], although more recent data [16, 38, 39] show deviations.

$$\log K_p = \frac{5186.5}{T} + 0.611\log T - 6.75$$

where T= temperatue in K

Influences on the Conversion Equilibrium. Any increase in the overall pressure will increase the extent of conversion at equilibrium, because the reaction leads to a decrease in volume.

The maximum possible equilibrium sulfur dioxide conversion at a given temperature T and total pressure p depends upon the SO_2 and O_2 concentrations of the supplied gases. If the sulfur

dioxide concentration is $2a$ vol % and the oxygen concentration b vol %, the fraction x of sulfur dioxide oxidized to sulfur trioxide at equilibrium can be calculated from the following equation based on the law of mass action:

$$K_p = \frac{1}{\sqrt{p}} \frac{x}{1-x} \sqrt{\frac{100-ax}{b-ax}}$$

The appropriate value of K_p is determined from the equation of Bodenstein and Pohl. The dependence of SO_2 equilibrium conversion on temperature and pressure is shown in Figure 10 for the example of sulfur combustion gas containing 10 vol % SO_2.

Figure 10. Theoretical conversion equilibrium in the oxidation of SO_2 to SO_3 as a function of temperature and pressure (feed gas composition: 10 vol % SO_2, 10.9 vol % O_2)
a) 10 bar; b) 8 bar; c) 5 bar; d) 1.3 bar

In accordance with the law of mass action, increasing the oxygen partial pressure will also increase the degree of conversion. However, when air alone is used as the source of oxygen in SO_2 production, as is usually the case, the oxygen and sulfur dioxide concentrations are inversely related, so the greater the oxygen concentration in the combustion gases the lower will be the sulfur dioxide content. The essential factor determining the attainable SO_2 conversion is thus the volumetric O_2/SO_2 ratio in the feed gases. Whereas sulfur dioxide oxidation requires a stoichiometric O_2/SO_2 ratio of only 0.5: 1, in industry it is normal practice to use a ratio of at least 1: 1. The presence of excess oxygen not only raises the SO_2 equilibrium conversion but is also an essential prerequisite for maintaining the activity of the vanadium catalyst. There are, however, practical limits on the amount of extra air that can be added, because nitrogen present in the air dilutes the sulfur dioxide to the point where the economics of the process are impaired. Although it would be technically feasible to avoid nitrogen dilution by using oxygen instead of air, as is sometimes done in pyrometallurgical processes that produce high-strength byproduct sulfur dioxide gas streams, it is usually difficult to justify in a sulfur-burning installation [40].

Another practical expedient for improving the conversion of sulfur dioxide to sulfur trioxide is to remove, at an intermediate stage in the process, the sulfur trioxide already formed. In a double-absorption type sulfuric acid plant this is accomplished by routing the reaction gases after two of three stages of catalytic conversion through an intermediate absorption stage and then through one or two subsequent catalytic conversion stages. Because of the large (100 %) stoichiometric oxygen excess in the original feed gas and the diminished sulfur dioxide concentration, the O_2/SO_2 ratio at this point is about six times more favorable than at the start.

Influences on Reaction Rate. In an industrial plant, actual sulfur dioxide conversion never reaches the theoretical equilibrium value. Gas-phase oxidation of sulfur dioxide is kinetically inhibited, and virtually impossible at any temperature without a catalyst. At ordinary temperatures the reaction is so slow that, in practical terms, it does not occur at all. Increasing the temperature increases the rate of reaction, but simultaneously shifts the position of equilibrium in an unfavorable way – away from sulfur trioxide and toward sulfur dioxide and oxygen. Without a catalyst, the temperature required to make the system react at a practical rate is so high that conversion is very poor. Even with present-day catalysts, a temperature of ca. 400 °C is necessary to initiate a self-sustaining reaction.

The reaction mechanism varies depending on the catalyst used. Reaction with a platinum catalyst involves heterogeneous gas – solid catalysis

[22,23,26]. In contrast, according to present understanding, oxidation over a vanadium catalyst is a homogeneous reaction that takes place in a liquid melt of active components on both the external and internal surfaces of an inert solid catalyst carrier [41,42]. The reaction mechanism and the chemical structures of the active components have not yet been clearly defined. According to the model of MARS and MAESSEN [43], reaction in the melt takes place by way of the intermediate steps shown in Equations (12) and (13).

$$SO_2 + 2\,V^{5+} + O^{2-} \rightleftharpoons 2\,V^{4+} + SO_3 \quad (12)$$

$$0.5\,O_2 + 2\,V^{4+} \longrightarrow 2\,V^{5+} + O^{2-} \quad (13)$$

The validity of kinetic equations derived from this and other reaction models is limited to certain temperature ranges [44]. However, the rate of the catalytic oxidation of sulfur dioxide depends not only on the chemical mechanism but also on mass and heat transfer at the gas – liquid interface of the catalyst [42,45].

Figure 11. Comparison of (a) theoretical equilibrium SO_2 conversion for sulfur-burner gases (10 % SO_2, 10.9 % O_2) with (b) actual SO_2 conversion attained over a specific catalyst

Other purely technical parameters, such as the gas velocity, gas distribution, and residence time in the catalyst bed, help to determine how closely sulfur dioxide conversion in practice will approach the theoretical equilibrium. To estimate the sulfur dioxide conversion that can be achieved in reality in comparison with the thermodynamic equilibrium conversion, a correction function is used that takes into account the influences of the individual variables. Figure 11 is a plot against temperature of the theoretical sulfur dioxide equilibrium conversion and a typical observed sulfur dioxide conversion function. Actual conversion characteristics are significantly influenced by the specific catalyst activity, which must be determined empirically for each individual catalyst.

4.1.2. Catalysts [177]

Apart from catalyst activity, other factors including thermal stability, service life, and mechanical strength are of practical importance [20–23,42,44–47]. Of all substances tested for catalytic activity toward sulfur dioxide oxidation, only vanadium compounds, platinum, and iron oxide have proven to be technically satisfactory. Today, vanadium pentoxide is used almost exclusively.

Commercial catalysts contain 4 – 9 wt % vanadium pentoxide, V_2O_5, as the active component, together with alkali-metal sulfate promoters. Under operating conditions these form the liquid melt in which the oxidation of sulfur dioxide is thought actually to take place. Potassium sulfate is used most often in a K/V molar proportion of ca. 2.5 – 3.5. Some catalysts also contain sodium sulfate to reduce the melting point. The carrier material is silica in the form of diatomaceous earth, silica gel, or zeolites, all of which present especially large specific surface areas. Cesium-doped catalysts have also been developed and installed in various facilities. Cesium sulfate as a promoter reduces the melting point of the active components, resulting in significantly lower temperature limits for sustainable stable activity.

The catalyst components are mixed together to form a paste, which is then usually extruded into solid cylindrical pellets or rings. These are dried and baked at elevated temperature. Other catalyst forms less common in industry include spheres and tablets. Pellet-type catalysts were used almost exclusively until the mid 1980s, but plants today are usually equipped with ring-

shaped (or "star-ring") catalysts. The advantage of a ring-type catalyst is a lower pressure drop; compared to pellet-type catalysts the pressure drop is reduced by more than half. Furthermore, a ring-shaped catalyst is less sensitive to dust blockages. The relationship linking gas velocity with pressure-drop for different catalyst forms is illustrated in Figure 12.

Figure 12. Pressure drops for various catalyst types per meter of catalyst depth (BASF)
a) Pellets (6 mm); b) Rings (10/5 mm); c) Star-rings (11/4 mm)

Operating Temperature Range. An important property of the vanadium catalyst is the low-temperature limit at which stable operation is possible under fixed gas conditions. This temperature is ca. 410 – 430 °C for a conventional catalyst and ca. 380 – 390 °C for a cesium-doped catalyst. Low-temperature activity depends mainly on the melting point and the chemical properties of the mixture of active constituents.

The upper operating-temperature limit is determined by the thermal stability of the catalyst. Above ca. 600 – 650 °C catalyst activity may be lost irreversibly because of damage to the structure of the carrier and reduction of its internal surface.

Service Life. The average service life quoted by most catalyst producers [46] is about ten years. Service life is generally determined not so much by progressive loss of activity as by catalyst losses incurred when filling and emptying the reactor and during routine screening. Depending on the dust load of the gas entering the converter, the size and shape of the catalyst grains, and the properties of the active melt, dust will accumulate in the catalyst bed over the course of time. This dust eventually increases the gas-pressure drop through the catalyst bed and reduces both gas throughput and SO_2 conversion efficiency. That is the reason why the catalyst must be screened from time to time to remove dust [48]. When catalyst is withdrawn, screened, and returned to the reactor, a certain amount is bound to be lost as a result of abrasion. The precise amount depends on the handling method used and the stability of the catalyst. This loss must be compensated by the addition of new catalyst.

In contrast to platinum, vanadium catalyst is largely insensitive to catalyst poisons [49]. Fluorine compounds in elevated concentrations will attack the carrier material, leading to increased abrasion loss. Chlorine compounds, especially at elevated temperatures, will volatilize the vanadium and consequently decrease the activity. Arsenic, which may be present in the feed gases that result from roasting arsenical pyrites, will accumulate in the catalyst, but it will only cause an observable decrease in activity if the As_2O_3 concentration in the catalyst mass exceeds 15 wt % [20].

Water vapor in the feed gas is not deleterious to a vanadium catalyst so long as the temperature is sufficiently high to prevent condensation of sulfuric acid. At low temperature (during plant stoppages, for example, or when the catalyst is exposed to humid air) there is a danger that water will be absorbed by the hygroscopic active constituents, and this can impair the mechanical strength of the catalyst.

4.1.3. Process Summary

There are four main process steps in the production of sulfuric acid from sulfur dioxide-containing gases by the contact process:

1) Gas drying

2) Catalytic conversion of sulfur dioxide to sulfur trioxide
3) Absorption of sulfur trioxide
4) Acid cooling

The gas-drying stage is not applicable to a plant of the wet-catalysis type. Almost without exception, contact plants operate under essentially atmospheric pressure; compression is required only for driving the gases through the plant.

4.1.3.1. Gas Drying

Gas drying is an important process step in conventional contact plants (in contrast to wet-catalysis plants). It protects cooler parts of the plant, such as heat exchangers, against corrosion by acid condensation, and it safeguards against the formation of sulfuric acid mist, which can be very difficult to absorb. It also protects the catalyst from ill effects of acid condensation when the plant is shut down for any reason. Therefore, both the operating performance (especially tail-gas purity) and the service life of the plant depend in large measure on an efficient and reliable gas-drying stage.

In sulfur-burning plants the molten sulfur used is dry from the outset, because its melting point is well above the boiling point of water, and any moisture originally present will have been driven off in the melter. The combustion air, however, must be dried. In the usual arrangement, filtered air from the atmosphere is drawn through a drying tower by the main blower.

When the feed gas is derived from smelter waste gases or pyrite roasting, cold, humid, sulfur dioxide-containing gas from the gas-cleaning system (→ Sulfur Dioxide, Chap. 6.) is mixed with such additional air as may be required to bring the O_2/SO_2 ratio to the optimum process value before the gas mix enters the drying section. Similar gas-drying equipment is used in both situations.

The gases are in most cased dried in countercurrent with fairly concentrated sulfuric acid in irrigated packed towers [20–22]. The sulfuric acid is circulated. The residual water content of the gases after drying corresponds theoretically to the partial pressure of water vapor above the drying-tower acid at the prevailing temperature and concentration. For purposes of achieving a high drying efficiency, the temperature of the irrigation acid is normally maintained at 50–60 °C.

A substantial amount of heat – not simply the heat of dilution of the sulfuric acid but also the heat of condensation of the water – is liberated in the gas-drying stage. For this reason the circulated acid is generally cooled by indirect heat exchange before returning to the dryer.

Water Balance. The sulfuric acid concentration of dryer acid is usually between 93 and 98 %, depending on the production conditions and the plant concept. This level is maintained constant by bleeding off part of the dilute acid leaving the dryer and exchanging it for a corresponding amount of concentrated acid (98.5 %) from the absorber circuit. When the desired product-acid strength is 93 – 95 % H_2SO_4, product acid can be taken directly from the drying circuit. In the case of a sulfur-burning plant, process water may even need to be added to the drying acid circuit to prevent the acid concentration from rising, and it is then not necessary to transfer dryer acid back to the absorber circuit. Occasionally, 98 % acid is used in the drying tower; this arrangement permits a common pump tank to be used for both dryer and absorption circuits instead of the usual separate pump tanks [50].

Water absorbed by the dryer acid is thus used as process water for sulfuric acid formation because of connections between the dryer and absorption systems. When processing metallurgical off-gases, the water content of the feed gas entering the dryer must be controlled by cooling in the gas-cleaning plant so that it does not exceed the stoichiometric requirement for production of H_2SO_4 based on the amount of SO_3 to be absorbed. Otherwise, the water balance in the contact plant will not be maintained, and the concentration of circulating acid will drop below the minimum level required for proper plant operation.

The permissible water content for feed gases is determined by the concentration of the product acid, the sulfur dioxide content of the contact gases, and the sulfur dioxide conversion efficiency. Figure 13 illustrates how the allowable feed-gas moisture content (represented by the gas temperature at the inlet of the drying tower, to which is is related) varies with sulfur dioxide

content for two different product-acid strengths. It can be seen that the lower the sulfur dioxide content of the gas, the cooler (i.e., the less moist) the gas must be before it enters the drying tower.

Figure 13. Maximum permissible temperature of moist gas at drying tower inlet of a roaster gas-based double-absorption sulfuric acid plant as a function of gas SO_2 content and desired product acid strength
a) 93 % H_2SO_4 product; b) 98.5 % H_2SO_4 product

In the case of metallurgical gases with extremely low SO_2 concentrations it is sometimes technically difficult and uneconomical to cool the feed gas to the low temperature required to maintain the correct water balance. For such cases Lurgi has developed a predryer-reconcentrator system that has been proven in service [51]. In the predryer, upstream from the main drying tower, surplus water is removed from the metallurgical gas by washing with sulfuric acid of medium concentration (30 – 60 %). This acid does not circulate to the main acid-plant dryer and absorber circuit. Instead, it circulates in a closed circuit between the predryer and a reconcentrator immediately downstream from the final SO_3 absorber in the main acid plant, where itgives up moisture to tail gas released to the atmosphere (see the description of the venturi process in Section 4.3.2). Alternatively, a water refrigeration plant would be required to adjust the gas temperature to the appropriate level.

Drying-Tower Design. The dryers used today are, as a general rule, vertical cyclindrical towers. Their steel shells are lined with acid-proof bricks. In the lower part of most such towers a plastic foil (polyisobutylene) is applied between the steel shell and the bricks in order to prevent acid from penetrating through the bricks to the steel shell. A grate of acid-proof material supports the packing. Normally, Raschig rings or Intalox saddles of ceramic material are used as packing. The dryer design is determined by a number of interacting parameters, such as the surface character and geometry of the packing, the packing height, the gas velocity, and the irrigation rate. The efficiency of moisture absorption by the sulfuric acid depends mainly on the diffusion resistance at the gas – acid interface. The gas flow velocity is best kept well above the region of laminar flow, because this induces turbulence that not only lowers the diffusion resistance but also improves distribution of the liquid.

A lower limit on the irrigation density is set by the minimum amount of acid required for uniform wetting of the entire packing surface. The maximum level is defined by the flooding limit, which is itself a function of the gas velocity, and must be determined empirically for each packing type.

An important factor in ensuring uniform acid distribution over the entire tower cross-section is the nature of the acid irrigation system. Preferably, this should be located in the upper part of the packing layer, and it should consist of cast iron or stainless steel nozzle tubes with lateral oblique openings directed upward. As a general rule, a wire-mesh filter of plastic or stainless steel is installed above the packing layer to separate entrained acid droplets.

Normally, a residual moisture content of 50 mg/m^3 in the dry gas is considered satisfactory.

4.1.3.2. Catalytic Oxidation of Sulfur Dioxide

The reactor in which sulfur dioxide is oxidized catalytically to sulfur trioxide is known as the *converter*. It is the heart of the sulfuric acid plant.

In the design and construction of any converter intended to assure maximum sulfur dioxide conversion, proper attention to removal of the very considerable reaction heat is of vital importance. The reaction is generally carried out under adiabatic conditions, so the temperature of the solid catalyst bed rises, thereby determining, and at the same time limiting, the attainable level of SO_2 conversion consistent with thermodynamic equilibrium (see Fig. 10). To achieve a

high final SO_2 conversion, the total catalyst mass is divided up into several catalyst beds (trays), and hot gas leaving each bed is cooled to the minimum working temperature of the catalyst before it enters the next bed. Tubular converters operating at nearly isothermal conditions have now almost completely fallen out of use in sulfuric acid plants. Isothermal fluidized bed converters are under development, however, and some have reached the point of industrial use.

Figure 14. Comparison of reaction profiles and SO_2 conversion for 4-bed normal contact (single absorption) and (2 + 2) double-absorption processes (feed gas: 8.5 vol % SO_2)
a) Double-absorption process equilibrium curve after intermediate absorption; b) Equilibrium curve for normal contact process; c) Adiabatic reaction in bed 1; d) Adiabatic reaction in bed 2; e) Cooling and intermediate absorption; f) Cooling; g) Bed 3; h) Bed 4

Figure 14 shows the reaction profile for a converter comprising four beds and operating under adiabatic conditions, together with the SO_2 conversion attainable in each bed within the general limits of actual conversion characteristics. A profile for the normal contact process without intermediate absorption (single absorption) is compared with that for a double-absorption process with intermediate absorption after the second bed. It is evident that the overall conversion ultimately obtained in the double-absorption process is substantially greater than in a single-absorption process with the same number of catalyst beds. In the single-absorption process, the maximum achievable SO_2 conversion with a typical four-bed converter is ca. 98 %. (The exact figure depends on the feed-gas composition.) This contrasts with a final SO_2 conversion > 99.5 % in the double-absorption process.

The normal configuration for a double-absorption plant using a fixed-bed converter is either (2 + 2) or (3 + 1). That is to say, the intermediate SO_3 absorber can be placed after either the second or the third bed. If an SO_2 conversion efficiency > 99.7 % must be guaranteed, a five-bed converter in a (3 + 2) or (4 + 1) configuration may be preferred [52]. Further improvements in conversion efficiency, especially in a single-catalysis plant, can be achieved with cesium doping (see Section 4.1.2). The resulting considerable increase in low-temperature activity permits a conversion efficiency of ca. 99 % in a single-catalysis plant and > 99.7 % in a double-catalysis plans. However, the applicability of such catalysts is limited by high cost.

The double-absorption method has another significant advantage as well, in that it can process feed gases with a higher sulfur dioxide content and correspondingly lower O_2/SO_2 ratio than the single-absorption process. On account of a lower specific gas-flow rate for a given nominal H_2SO_4 production capacity, equipment for the double-absorption process can also be smaller.

Converter Design. The process design for a converter [22, 45] requires careful optimization because of the large number of interacting parameters. It has been considerably simplified by the development of appropriate computer programs [53–55]. The most important variables are the sulfur dioxide concentration and gas-flow rate, the number of beds, the specific catalyst quantity and its distribution between the individual beds, the gas-pressure drop, and the gas-inlet temperatures at the individual beds. In arriving at a final design, due consideration must be given to the relationship between equipment costs and energy costs.

The specific catalyst quantity required for production of 1 t/d of sulfuric acid is ca. 200 – 260 L for a "normal" contact (single-absorption) plant and about 150 – 200 L for a double-absorption plant. The distribution of the catalyst bet-

ween the individual beds can vary widely as a function of the gas concentration and the way the gas is routed. The catalyst bed height may vary from ca. 200 mm to 1000 mm. Different catalysts may also be used in different beds; the choice depends on the thermal stresses prevailing at each stage. The preferred grain size depends on pressure-drop considerations and the permissible dust load.

The optimum method of cooling the reaction gas between the catalyst beds is a function of the composition and initial temperature of the feed gas, and thus its origin. It is normally preferable to use indirect heat exchange. In a "cold-gas" plant running on off-gases from a metallurgical or spent-acid decomposition plant, virtually all the surplus reaction heat is transferred to the feed gas in a series of gas – gas heat exchangers to raise the gas temperature to the reaction temperature of the first catalyst bed. Modern plants processing gases with higher SO_2 loads (> 8 vol %) are equipped with boiler elements as a way of removing excess reaction heat. This improves the overall energy efficiency and maintains the gas temperature at the inlet of the absorption tower within reasonable limits. In a sulfur-burning plant, where the feed gas is already hot, surplus reaction heat from the catalytic section is recovered in steam generators and boiler feed-water preheaters (economizers). In all double-absorption plants, however, gas passing from the converter to the intermediate absorber and back is cooled and reheated in indirect gas – gas heat exchangers. Direct injection of cold feed gas or quench air may be employed to a limited extent under certain circumstances, either after the first catalyst bed for the purpose of limiting the outlet gas temperature and thus the thermal stress on the first heat exchanger or steam generator, or in later stages if the amount of available heat is insufficient to warrant provision of an indirect heat exchanger or feed-water preheater.

The idea of mounting at least some of the heat exchangers inside or around the converter shell has become attractive once again even though it was abandoned in the 1970s and 1980s. Converters fabricated entirely of stainless steel provide sufficient flexibility from a design and construction standpoint to permit such heat exchangers to be incorporated into the converter vessel. The advantage of this arrangement is of course elimination of some of the gas ducts, including expansion joints, supports, etc. However, no general rule is available to cover all types of plants; the design engineer must consider carefully the relative advantages of fewer gas ducts versus a more complicated converter vessel.

Normally, the converter is designed as a vertical cylindrical vessel, with the catalyst beds mounted above one another in separate, virtually gas-tight compartments. Gases enter and leave through lateral nozzles, passing upward and downward through the beds.

The catalyst mass is supported by a metallic bed grate. A base layer of ceramic packing prevents direct contact between the catalyst and the grate, which could give rise to corrosion. The catalyst bed is itself covered with another layer of packing. This serves the dual purpose of helping to ensure uniform gas and temperature distribution over the surface of the catalyst and preventing the catalyst from blowing around and leaving cavities in the bed, which might also adversely affect gas and temperature distribution in the main body of the catalyst bed. The converters are usually lined with ceramic material in the catalyst areas.

Three principal types of converter are in use: stainless steel (with or without heat exchangers), steel, and brick-lined [56].

The *stainless-steel converter* (Fig. 15, see next page), consisting of the shell, the tray separators, and the trays, is fabricated entirely of stainless steel or heat-resistant steel. A central tube is often used to support the trays. Heat exchangers (also made of stainless steel) can either be incorporated into the central tube or arranged around the shell.

The *steel converter* (Fig. 16, see next page) corresponds in principle to the stainless-steel converter, but boiler plate or equivalent is used as the construction material for the shell, the separations, and trays for those layers with lower operating temperatures. A steel converter is more economical compared with a stainless-steel converter and is appropriate for treatment of gases with lower SO_2 loads.

The *brick-lined converter* (Fig. 17, see following page) is completely lined internally with acid-proof bricks. The compartment separators are self-supporting domed structures made of

Figure 15. Lurgi converter in stainless steel with integrated heat exchangers

shaped bricks. These carry brick columns that support the catalyst-bed grates. The brick-lined converter represents a conservative design guaranteeing long lifetime together with a high "thermal inertia." This facilitates operation with fluctuating gas loads as well as start-up after idle periods.

Figure 16. Four-bed all-steel converter

The *cast-iron converter* that for many years constituted the standard design – specifically in the United States – has now been practically eliminated from sulfuric acid plants.

Tubular converters (→ Tubular Reactors), which were in common use in sulfuric acid plants until the 1960s, have the inherent advantage over bed converters that reaction conditions can be made almost isothermal, but they are quite unsuitable for use in today's large-capacity acid plants on account of several seri-ous disadvantages. In particular, in order to ensure that heat is dissipated efficiently from the catalyst it is necessary to use a large number of narrow-diameter tubes, even for small plant capacities. It is difficult to change the catalyst charge in such tubes, gas distribution is difficult to control, and the risk of corrosion is increased because catalyst is in direct contact with the tube material.

These shortcomings are not shared by the *fluidized-bed converter*, which also operates under virtually isothermal conditions. The good heat-transfer characteristics of a fluidized bed are well known (→ Fluidized-Bed Reactors). It is possible to conduct sulfur dioxide oxidation in this way at a constant temperature in the optimum operating range of the catalyst. The released heat of reaction is removed from the fluidized bed by immersed tube bundles that generate steam. One great advantage of the fluidized-bed converter is that cold feed gases from metallurgical processes or other sources need not be preheated to the reaction temperature; instead the conditions in the fluidized bed are simply adjusted to provide any heat necessary to the incoming gas. A further attraction of this type of converter is that it can process feed gases with much higher sulfur dioxide concentrations relative to a fixed-bed converter [57].

Because of the favorable thermodynamic conditions in a fluidized-bed converter, the conversion attainable in a single stage may equal that achieved in the first three beds of a conventional fixed-bed converter. The fluidized-bed converter is therefore ideally suited for use ahead of the intermediate SO_3-absorption stage in a double-absorption plant. However, itdoes require an extremely abrasion-resistant catalyst [58]. Bayer AG has developed a spherical catalyst for this purpose [59], and has used it in two fluidized-bed converter plants since 1971 and 1976, respectively, apparently with success [60].

4.1.3.3. Absorption of Sulfur Trioxide

Sulfur trioxide formed by the catalytic oxidation of sulfur dioxide is absorbed in sulfuric acid of at least 98 % concentration, in which it reacts with existing or added water to form more sulfuric acid [20–23]. The optimum concentration of the absorber acid corresponds to the azeotrope (see Section 2.1), where the partial pressures of SO_3, H_2SO_4, and water vapor are all at a minimum. At lower acid concentrations the water-vapor partial pressure is higher, and there is a correspondingly greater risk that sulfuric acid mist will form as a result of direct reaction of sulfur trioxide in the gas phase with water vapor above the acid. At acid concentrations above the azeotropic point the tail gas will contain increased amounts of sulfur trioxide and sulfuric acid on account of their higher partial pressures.

In the original contact (single-absorption) process, process gas passes through all the converter beds before the sulfur trioxide is absorbed

in a single absorption unit. In the double-absorption modification, now routinely practiced in both new and "revamped" plants, most of the sulfur trioxide is removed from the process gas in an extra absorption step at an intermediate stage. As explained above, this may occur after either the second or the third converter bed. In the (2 + 2) configuration, ca. 85 % of the original sulfur dioxide content of the feed gas has been converted to sulfur trioxide by the time the gas enters the intermediate absorber, and in the (3 + 1) configuration even more of the total amount of sulfur trioxide (ca. 93 – 95 %) is removed by the intermediate absorber. Sulfur trioxide formed in the last bed or beds from the small quantity of residual sulfur dioxide is absorbed in the final absorber.

Most absorbers are *packed towers*, usually operating in countercurrent. The gases pass from bottom to top through a bed of packing, which is uniformly irrigated from the top with concentrated sulfuric acid. Process gas leaving the converter system is cooled by a gas – gas heat exchanger or a steam generator, preferably in conjunction with a feed-water preheater, to a temperature of ca. 180 – 220 °C before entering the absorber. It is essential that the wall temperature in the gas coolers never drops below the acid dewpoint (ca. 110 – 160 °C, depending on the gas composition); otherwise, there is an acute danger of corrosion due to condensing acid, as well as mist formation. Gas entering the absorber is therefore not completely cold, and it releases heat to the absorber acid as it passes through the absorber; by the time it reaches the outlet it is at virtually the same temperature as the incoming absorber acid.

A substantial amount of heat is also generated in the absorber acid from absorption of sulfur trioxide and formation of sulfuric acid, and the acid temperature rises in consequence by an extent that depends on the acid-circulation rate. Efficient sulfur trioxide absorption depends not only on uniform acid and gas distribution in the absorber but also on ensuring that the temperature and concentration of the absorber acid remain at the optimum values. The acid concentration is held constant by adding process water or dryer acid to acid leaving the absorber, at a rate controlled by a device that measures the electrical conductivity or density. The optimum acid-inlet temperature depends on design conditions, but it is ca. 60 – 80 °C in most plants, maintained at that level by indirect cooling. The attainable SO_3 absorption efficiency is generally > 99.9 %.

Irrigated packed-tower absorbers are not efficient at removing *sulfuric acid mist* [1]. In spite of efficient gas drying and optimum conditions for sulfur trioxide absorption, it is often impossible to prevent mist formation completely, especially when processing high-bitumen sulfur or metallurgical feed gases with elevated hydrocarbon contents [61], or when starting up or shutting down the plant. Furthermore, in plants with an oleum tower upstream from the intermediate absorber, sulfuric acid mists may form with aerosol particle sizes in the submicron range owing to overcooling of the process gas. In such cases the mists may already have formed in the intermediate absorber. Ordinary wire-mesh spray separators have no effect on these mists, so special *mist eliminators* must be installed to avoid corrosion in the downstream heat exchangers and further mist formation in the final absorber. There are various designs for mist eliminators, and not all operate on the same principle. The most appropriate type depends on the nature of the mist, especially its particle size. For example, impingement separators are best for trapping particles above 1 – 3 μm, while submicron particles are more efficiently trapped by diffusion on Brownian-motion separators [61–65]. Glass fibers of varying degrees of fineness are preferentially used as the filter material.

The design principle underlying conventional absorption towers is similar to that for drying towers. Such towers have welded cylindrical steel shells lined on the inside with acid-proof bricks and silica-based, acid-proof mortar. Often the lower part of the tower around the acid sump is further protected by polytetrafluoroethylene (PTFE) sheeting sandwiched between the steel shell and the multilayer brick lining. As with the dryer, it is essential to ensure that gas and acid distributions are uniform over the entire tower cross-section, and that the acid flow rate is sufficiently high to wet the entire packing layer completely. Depending on gas conditions, the packing layer may have a height of 4 – 6 m.

The development of special stainless steels over the past few years has permitted the installation of steel absorption towers without any brick lining. This is a particularly great advantage when towers must be replaced during main-

tenance shut-downs. The absence of a brick lining means that a new tower can be completely prefabricated and set onto the existing foundations within a very short period of time.

Sulfur trioxide absorption systems based on *venturi scrubbers* were introduced by Lurgi in the early 1970s. These were developed specifically for the purpose of reducing heat losses during intermediate absorption so as to permit low-grade smelter off-gases to be processed autothermally in a double-absorption plant [40]. Because the gas and absorber acid flow in cocurrent in a venturi system, the gas temperature at the absorber outlet is higher than with a conventional countercurrent absorber based on acid at the same inlet temperature. Thus, less heat is transferred from the gas to the absorber acid for dissipation through the acid-cooling system. Running the absorber at a higher acid temperature reduces gas-heat losses still further. This principle of hot absorption in cocurrent with acid at a temperature of about 120 – 140 °C is useful not only for the purpose of processing low-grade feed gases but also for maximizing heat recovery generally in a double-absorption plant.

The venturi absorption system consists of vertical and horizontal venturi scrubbers arranged in series. In each case, acid is injected through a nozzle into the gas inlet of the venturi unit. Upon leaving the venturi units the gas passes through a packed tower where droplets entrained by the gases are separated.

The intensive mixing of injected acid with the turbulent gas stream in a venturi unit provides a large liquid – gas interface and, consequently, favorable mass- and heat-transfer conditions. This type of venturi system has given satisfactory service in many sulfuric acid plants, including units with H_2SO_4 capacities as great as 2000 t/d.

4.1.3.4. Acid Cooling

The acid cooling system plays a vital role in determining the efficiency and operating safety of an entire sulfuric acid plant. Appropriate choice of a particular cooling system depends not only on the acid temperature but even more on the availability and quality of the cooling water, as well as the cost of water in relation to the cost of energy.

The introduction of special stainless steels led to significant changes in the field of sulfuric acid cooling beginning in about 1980. Acid cooling in modern plants is dominated by two types of coolers:

1) Shell-and-tube coolers, either equipped with anodic protection or fabricated from special stainless steel that requires no such protection
2) Plate-type coolers

Intermediate closed-loop water circuits are also being installed more frequently both for heat recovery purposes and as a way of complying with environmental regulations (especially with respect to sea water). A further step has been the development of systems generating steam from heat released in the absorption system. A brief description of such systems is provided in Section 4.1.4.

Cast-iron cascade coolers, which were standard equipment for many decades, have been almost completely eliminated from modern acid plants; even in existing installations these coolers are in most cases being replaced. Decreasing reliability, poor quality, environmental regulations, and of course better alternatives have forced this development. The use of spiral coolers, tank coil coolers, etc., fabricated from "standard stainless" is limited to special applications. Air coolers occupy a share of the market in situations where the consumption of cooling water is restricted.

Shell-and-Tube Coolers. Shell-and-tube coolers offer many advantages, including ease of installation, compact design with correspondingly low specific space requirements, and good heat-transfer coefficients (ca. 800 – 1400 $Wm^{-2}K^{-1}$, 700 – 1200 $kcal\,m^{-2}h^{-1}K^{-1}$, depending on the design conditions and the mode of construction). Shell-and-tube (s + t) coolers made of stainless steel have been used in sulfuric acid plants since the mid-1960s when the introduction of anodic protection made this practical. At present, two types of s + t coolers are preferred:

1) Coolers fabricated from "standard" stainless steels and equipped with anodic protection systems

2) Coolers fabricated from special stainless steels (Sandvik SX, 1.4575, etc.), which do not require anodic protection

These coolers make it possible to cover the complete range of operating parameters normally encountered in drying and absorption systems. Sea water, brackish water, cooling-tower water, and closed-loop water can all be used as the cooling medium, provided appropriate materials are selected. In special cases, shell-and-tube coolers are made from other materials – Teflon or glass, for example – especially when aggressive media are being heated by the hot absorber acid, such as dilute or chemically contaminated spent sulfuric acid.

Plate Coolers. Ever since the development of adequate acid-proof gaskets, plate coolers have been increasingly called upon for sulfuric acid cooling duty. The sealing materials used today are elastomers such as Viton (a copolymer of vinyl chloride and hexafluoropropene; → Fluorine Polymers, Organic, Chap. 3.2.), which can handle acid at temperatures up to a maximum of ca. 110 °C. The special advantages of plate heat exchangers are extremely compact design, good accessibility, and easy maintenance and cleaning [66, 67]. They can be built with very thin walls, so the specific material requirement for the heat exchange area is very low, and the heat-transfer coefficient is very high (up to ca. 2300 $W\,m^{-2}\,K^{-1}$). Therefore, even expensive special materials can be used economically. Hastelloy C276 (DIN 2.4819) (→ Construction Materials in Chemical Industry, Chap. 5.3.3.), for example, has proved to be very satisfactory in plate heat exchangers designed for sulfuric acid cooling with brackish or sea water, although the water must be filtered carefully to avoid deposits in the plate cooler. For cases in which higher temperatures are required (e.g., for heat recovery purposes), an alternative type of plate cooler has been developed based on semiwelded plates. Pairs of welded plates form the sulfuric acid channels in these coolers, while plates with normal gaskets serve as the water channels.

Air Coolers. Air coolers are preferentially used in sulfuric acid plants when cooling water is not available in adequate quantity or at reasonable cost. The acid flows through tubes arranged horizontally in flat bundles, which are equipped with external fins to improve heat transfer. The cooling air is forced or sucked past the tubes by means of a fan. The tubes are usually made of stainless steel. The acid temperature is limited to ca. 80 °C unless the cooler is equipped with anodic protection, in which case higher temperatures can be tolerated [68]. Alternatively, if the cooler is equipped with acid-proof centrifugally cast tubes, acid temperatures up to about 110 °C can be handled.

Air coolers are relatively expensive to install, and a considerable amount of power is also required to drive the fans. However, in any cost comparison with water-cooled types the capital and operating costs of not only the acid-heat exchanger itself but also the requisite water-cooling system and water-treatment unit must be taken into account.

4.1.4. Practical Versions of the Contact Process

Contact sulfuric acid plants vary in a number of respects depending upon the raw material used to produce the sulfur dioxide-containing contact gases. The broadest division is into *hot-gas* and *cold-gas* plants. In hot-gas plants, which are usually based on the combustion of elemental sulfur, the hot feed gas from the sulfur furnace is cooled just to the required converter-inlet temperature. Cold-gas plants, based on metallurgical or decomposition gases, are so designated because the crude sulfur dioxide-containing gas must be cooled to low temperatures in the dedusting and cleaning systems before being introduced into the sulfuric acid plant. It is therefore necessary to reheat the cold feed gas to the requisite converter-inlet temperature with reaction heat from the converter system.

Cold-gas plants are sometimes confusingly described as "wet-gas" plants because cold feed gas leaving the gas-cleaning system is saturated with water vapor. However, this water vapor is removed by a dryer before the feed gas is preheated, so in all the remaining process steps the gas is effectively dry. By contrast, in a true wet-contact or wet-catalysis process, moist feed gas (produced, for example, by the combustion of hydrogen sulfide) is processed directly in the

converter without preliminary drying. Therefore, the term "wet" is best avoided when referring to a cold-gas plant.

These traditional contact-plant classes can be further subdivided into the double-absorption process (also referred to as the double-contact or double-catalysis process), which is the type of process now most commonly used in new plants, and the older, ordinary contact process, without intermediate absorption (also referred to as the single-catalysis or single-contact process) [69–76]. The ordinary contact process is still used where the feed gases are very low in SO_2 and where permitted by local pollution regulations. Within a given overall process concept, many variations in detailed design are possible [75–79].

4.1.4.1. Double-Absorption Process Based on Sulfur Combustion

The sulfur-burning double-absorption process is considered to be the standard sulfuric acid production process for conforming with sulfur dioxide emission limits now in force in most countries [52]. Heat is released in all steps. Whereas it has long been standard practice to utilize reaction heat from the converter for producing high-pressure steam, more recently it has become of economic interest also to recover low-level heat from the absorber and dryer-acid systems.

Process Description. Figure 18 is a flow diagram of a typical sulfur-burning double-absorption plant with a four-bed converter in the (3 + 1) configuration (intermediate absorption after the third bed), producing ca. 98.5 % sulfuric acid. The feed gas is produced by combustion of liquid elemental sulfur with dried air (→ Sulfur Dioxide, Chap. 4.). Air is drawn from the atmosphere through a filter and an air dryer (irrigated with concentrated sulfuric acid, see Section 4.1.3.1) into the main blower, which compresses it to a pressure of ca. 1.4 bar.

The combustion air flow is controlled in proportion to a predetermined sulfur feed rate so that gases of about 11 – 12 vol % SO_2 are produced by combustion. Combustion gas leaves the sulfur combustion furnace at about 1100 °C and is cooled in a waste-heat boiler to the converter-inlet temperature of ca. 420 – 450 °C. Under the adiabatic conditions prevalent in the first bed of the converter (Section 4.1.3.2), heat generated

Figure 18. Sulfur-burning double-absorption sulfuric acid process (Lurgi)

in the reaction raises the temperature of the gas mixture until it reaches a level at which the reaction is essentially in equilibrium. In practice, this corresponds to ca. 600 – 620 °C, representing a sulfur dioxide conversion of about 60 %. Passing out of the first bed of the converter, the gases are cooled in a steam superheater to the second-bed inlet temperature of 430 – 440 °C. The gas leaving the second bed is cooled in the evaporator of the steam system to the third-bed inlet temperature, ca. 420 – 440 °C. Gas leaving the third bed is cooled in two intermediate heat exchangers and passes at ca. 200 – 220 °C into the intermediate absorber, where sulfur trioxide is removed by absorption in concentrated sulfuric acid (Section 4.1.3.3). The remaining gas, which is cooled in the absorber to about 70 – 80 °C, is returned to the intermediate heat exchangers through a heated double-jacket tube to avoid the condensation of sulfuric acid. The cold gas is heated indirectly by hot gas from the third bed to the inlet temperature of the fourth bed (ca. 400 °C). The hot gases coming from the fourth bed are cooled to ca. 160 °C in an economizer (feed-water preheater) and passed into the final absorber. After final absorption, so-called tail gas is discharged to the atmosphere through a stack at ca. 70 – 80 °C. An overall sulfur dioxide conversion efficiency of ca. 99.7 % is attainable in this type of plant. Assuming the feed gas contains 10 vol % SO_2, this corresponds to a sulfur dioxide concentration in the tail gas of about 400 ppm SO_2.

Figure 18 also shows the acid circuits for the air dryer and the intermediate and final absorbers. In this example, the end product is 98 – 98.5 % sulfuric acid, which is discharged from the final absorber circuit. Water required for maintaining the correct acid concentration, apart from that absorbed in the air dryer, is supplied as process water to the absorber acid system. Water addition is controlled automatically by an acid-concentration measuring system operating within narrow limits (Section 4.1.3.3). The dryer-acid circuit is designed to discharge sulfuric acid of 93 – 97 % concentration back to the absorber circuit. If part of the production is to be discharged as oleum (see Section 4.4), and additional oleum tower is added upstream from the intermediate absorber. Plants designed for maximum oleum production preferentially reflect the (3 + 2) configuration. Five-bed converter systems with (3 + 1) configurations are used especially for achieving maximum final conversions [44, 72–74, 80].

Sulfur-burning double-absorption plants are designed for production capacities $\leq$ 3000 t/d of 100 % sulfuric acid in a single stream [81].

Energy Balance. All steps in the production of sulfuric acid from elemental sulfur are exothermic. An amount of heat corresponding to about 5.4 GJ is generated overall per ton of 100 % sulfuric acid. The thermal capacity of a sulfuric acid plant with an output of 1000 t/d H_2SO_4 is, accordingly, ca. 63 MW. The liberated heat must be dissipated under controlled conditions in such a way as to maintain optimum gas temperatures in the converter system and optimum acid temperatures in the dryer and absorber circuits, thereby ensuring that sulfur dioxide concentrations in the tail gas are minimized and sulfuric acid mist and sulfur trioxide at the stack outlet are avoided insofar as possible. The systems for gas and acid cooling are therefore essential components of a sulfuric acid plant.

Figure 19 shows the energy flow in the form of a Sankey diagram for a double-absorption plant of the type represented by Figure 18 [75]. Of the total energy input (100 %), 97 % is accounted for as energy released in the conversion of sulfur to sulfuric acid, and 3 % of the energy is consumed in driving the gas through the plant. Up to about 70 % of the total energy is normally utilized for the generation of ca. 1.35 t of high-pressure steam (40 bar, 400 °C) per tonne of sulfuric acid; the remaining 30 % is usually lost as waste heat.

The high-pressure steam is generated with high-temperature heat recovered by indirect exchange with gases from the converter system and the sulfur furnace. The waste-heat system is completely integrated into the double-absorption sulfuric acid plant (Fig. 18). In the economizer that cools the gases from the fourth bed, about 13 % of the overall process heat is utilized for feed-water preheating. The waste-heat boiler downstream from the sulfur furnace and the evaporator after the second bed use respectively 38 % and 16 % of the total heat to produce saturated steam. Another 10 % of the total energy is recovered in the steam superheater after the first bed for the generation of high-pressure steam.

Of the generally unrecovered waste heat, the majority (31 % of the total energy) is removed in the acid-cooling systems: 1 % in the dryer circuit, 24 % in the intermediate absorber circuit, 5 % in the final absorber circuit, and 1 % in the product-acid cooler. Heat in the dryer results from the condensation of water vapor and the dilution of sulfuric acid. Heat from the absorbers is made up of sensible heat transferred from the moderately hot gas to the colder acid in the absorber, the latent heat of condensation of sulfur trioxide, and the heats of formation and dilution of sulfuric acid. A small amount of the total energy is discharged from the system as sensible heat in the tail gas (2.5 %) and in the product acid (0.5 %).

Maximizing Energy Recovery. The value of energy has risen so much that systems for maximum energy recovery are becoming increasingly economical despite the associated considerable increase in capital cost. This is especially true for the extremely large-capacity double-absorption sulfuric acid plants now in use.

In the *steam system*, it is possible to improve energy utilization not only by increasing the production of high-pressure steam but also by optimizing the steam quality [76–78]. Use of a specially designed waste-heat system makes it possible because of the high excess temperature of the gas to produce steam at up to 80 bar in a sulfuric acid plant instead of the normal 40 – 50 bar. The higher the quality of the steam the more efficiently it can be converted into mechanical work or electrical energy. Production of high-grade steam is advantageous even if low-pressure steam for heating purposes is all that is required in neighboring production plants. In this case the high-pressure steam can be transformed into low-pressure steam in a back-pressure turbine driving a generator or other equipment [82, 83]. The Lurgi substoichiometric sulfur-combustion system (→ Sulfur Dioxide, Chap. 4.4. is well suited to the generation of highgrade steam, and it has been used successfully in a number of modern sulfuric acid plants [77].

Steam production can be increased by raising the acid and gas-outlet temperatures in the intermediate absorber to reduce gas-heat losses. As a general rule, hot converter gas is cooled before entering the intermediate absorber by indirect exchange with cold gases returning from the

Figure 20. Absorber acid heat-recovery system with intermediate closed-loop hot water circuit

same absorber. The gas exit-temperature from the intermediate heat exchanger is usually too close to the acid dewpoint for the recovery of any more heat for steam generation. Otherwise there would be a danger of sulfuric acid condensing, which would give rise to corrosion on the heat-exchange surfaces as well as mist formation. However, use of venturi-type cocurrent absorbers and the hot absorption principle permits the gas temperature after the intermediate absorption stage to be increased substantially (see Section 4.1.3.3). Thus, the amount of heat required for heating the cold gases from the intermediate absorption stage is reduced. At the same time, an adequate amount of heat at sufficiently high temperature becomes available in the sulfur trioxide-rich gas upstream from the intermediate absorber to run an evaporator or economizer (feed-water preheater) integrated within the steam system. This can be located either before or after the intermediate heat exchangers. It is possible to boost steam production in the sulfuric acid plant by an additional 10 % by preheating the boiler feed water to about 90 °C, utilizing waste heat in acid from the absorption systems.

If recovery of acid waste heat is to be optimized, the temperatures in the absorption systems become very important. Raising the temperature creates more favorable conditions and a wide range of possibilities for heat utilization. The extent to which the acid temperature can be increased is restricted largely by the allowable corrosion rate in the heat exchangers. Considerable advances have been made in recent years in the development of special materials and techniques for controlling corrosion at higher acid temperatures. A number of double-absorption plants now incorporate acid-cooling systems modified for heat recovery and utilization. The required investment can be amortized within a short time out of energy cost savings.

Figure 20 shows one possible combination of various approaches to utilizing recovered acid waste heat [77, 84]. The heat recovery system depicted has been installed in a preexisting sulfur-burning double-absorption plant. The heat is used to produce boiler feed water by distillation of seawater, for boiler feed-water preheating, and for preheating filter wash water for a neighboring phosphoric acid plant. Heat is transferred from the anodically protected stainless-steel acid cooler to the various consumers by means of a closed-loop hot water circuit.

In other sulfuric acid plants, waste heat recovered from the acid is utilized in hot water circuits for remote heating [85]. In plants operating with absorber acid at elevated temperature (130 – 140 °C), waste heat from the acid is also used for concentrating phosphoric acid from 28 – 54 % P_2O_5 (Fig. 21). Other plants use acid

waste heat for reconcentration of spent sulfuric acid in a venturi system (see Section 4.3.2) [75, 84].

A significant step toward more highly energy-efficient plants was taken with the introduction of heat recovery systems generating steam from the acid circuit. Thus, part of the heat formed in the absorption circuits (and normally dissipated with the cooling water) is transferred to a higher level and used for the production of low-pressure steam at 6 – 10 bar. Depending on the nature of the plant, up to 0.5 t of steam per tonne of acid can be produced in this way in addition to the high- or medium-pressure steam obtained from a sulfur-burning plant. The overall energy efficiency is thus increased to $> 90\,\%$ based on a "standard sulfur-burning" plant [178, 179].

Such heat recovery systems are normally installed in the intermediate absorption circuits. Intermediate absorption is divided into two stages: a first stage operated at ca. 180 – 200 °C and a second stage at a "normal" absorption temperature of ca. 80 °C. About 95 % of the incoming SO_3 is absorbed in the first stage, where no sensible heat is removed from the gas. Acid is circulated at ca. 180 – 200 °C; the heat, which is a result of absorption/acid formation, is transformed into steam in a special boiler, usually of the kettle type. In the second stage, remaining SO_3 is absorbed and the gas is cooled to ca. 80 °C in order to provide appropriate gas conditions for downstream plant elements. Heat formed in the second stage absorber is normally used for boiler feed-water preheating or other heating purposes.

At present, two such systems are available on the market, representing different approaches to realizing the desired end:

1) The Monsanto HRS system
2) The Lurgi low-pressure steam recovery system

The Monsanto HRS system is based on investigations showing that "normal" stainless steels are subject to low corrosion rates when the acid concentration is $> 99\,\%$. That "window of concentration" permits the design and construction of a system consisting of 300-grade stainless steel and incorporating a first-stage absorption tower (with a countercurrent flow absorber, piping, heat exchanger, etc.). No brick lining is required. It is self-evident that the acid concentration must be carefully controlled, but this is quite feasible with modern instrumentation. The second-stage absorption circuit corresponds in principle to a standard absorption system. A typ-

Figure 22. Monsanto heat recovery system

ical flowsheet for a Monsanto HRS system is shown in Figure 22.

Lurgi has taken a different approach for its low-pressure steam recovery system. In cooperation with Thyssen and Krupp-VDM, a stainless steel was qualified for sulfuric acid service over a relatively wide range of concentrations and temperatures (see Fig. 23). The material is a ferritic stainless steel with the German material code 1.4575 and known as Superferrit (Thyssen) or Cronifer 2803 (Krupp-VDM). This material provides excellent corrosion resistance, but handling and equipment fabrication require special precautions because of brittleness. Lurgi has chosen here to again make use of its venturi absorption systems, already familiar from other sulfuric acid plant applications (see Section 4.3.2). The venturi unit constitutes the first-stage absorber, to which a separate acid circulation system is connected, including a pump tank, pumps, piping, etc. Heat generated in this system is transformed into low-pressure steam in a specially designed boiler. Second-stage absorption takes place in a small packed tower connected to the venturi unit. The venturi unit, the pump tank, the heat-exchanger tube bundle, piping, etc., are all fabricated from 1.4575 steel. Alternatively, the venturi unit and pump tank can be of a standard design: mild steel with a brick lining. A simplified flow diagram is provided in Figure 24.

Figure 23. Range of application for Superferrit 1.4575 in concentrated sulfuric acid

With respect to the pumps, valves, etc., special cast alloys have been developed for the required high-temperature service. Additional facilities, such as continuous corrosion measurement and noise monitoring systems, are available for such heat-recovery systems as accessories to facilitate monitoring of all the relevant process data.

Figure 24. Low-pressure steam recovery system

Pressure-Contact Process. A specific variant of the sulfur-burning double-absorption process is the pressure-contact process, in which sulfur combustion, sulfur dioxide conversion, and sulfur trioxide absorption are all effected at elevated pressure. The idea of conducting a contact process under pressure is not new – it was first suggested over 50 years ago [86] and the notion has since been reiterated from time to time [87–91]. So far, however, is has only been embodied in one industrial double-absorption plant with a capacity of 550 – 575 t/d H_2SO_4 operated by PCUK in France [92–94]. The maximum pressure in this plant is 5 bar. It first assumed operation in 1972.

After drying in a conventional tower under normal pressure, combustion air is compressed to 5 bar for introduction into the sulfur furnace. Liquid sulfur is supplied through a special burner, and it burns at a maximum temperature of 1800 °C. The combustion gas, containing about 12 vol % SO_2 and 9 vol % O_2, is introduced at ca. 1200 °C into a fire-tube waste-heat boiler, after which it passes through a gas filter before being subjected to three stages of conversion in separate converter vessels. The process gas is then cooled and introduced into the intermediate absorption stage. Downstream from the intermediate absorber there is one further converter, from which gas passes to the final absorber. Tail gas leaving the final absorber is reheated and expanded in a turbine coupled with the air compressor. It is asserted that about two-thirds of the compression energy is recovered in this way [93].

As in an atmospheric-pressure double-absorption plant, the process gas is cooled in gas – gas heat exchangers before entering the intermediate absorber. In the pressure-contact process, however, only one exchanger is used for reheating cold gas returning from the intermediate absorber to the fourth converter stage. Another one serves to reheat the tail gas from the final absorber before it enters the turboexpander. Heat is recovered for steam generation in economizers, positioned downstream from the fourth converter and the expansion turbine, as well as in a waste-heat boiler after the sulfur furnace.

Compared with a conventional double-absorption process, two special advantages have been claimed for the pressure-contact process:

1) The position of chemical equilibrium in the sulfur dioxide oxidation reaction (Eq. 10) is more favorable, permitting a higher conversion efficiency with less catalyst. The PCUK plant is reported to have achieved 99.8 – 99.85 % conversion with a catalyst charge of only about 76 L per tonne of daily sulfuric acid production capacity [93]. The tail-gas sulfur dioxide content is reported to be reduced to about 200 – 250 ppm by volume. However, the high temperature in the sulfur furnace increases the rate of nitrogen oxide formation (→ Sulfur Dioxide, Chap. 4.4.).
2) On account of the lower operating volume with respect to the converter gases, smaller equipment can be used. This reduces the material and site-area requirements, and it raises the capacity limit on shop-fabricated equip-

ment. The resulting capital and construction cost savings are said to be ca. 10 – 17 % relative to a typical double-absorption plant [93]. It should be mentioned, however, that these savings would be nullified in many countries by the cost of conforming with requirements for extra wall thickness and higher-grade construction materials arising from safety regulations regarding pressure vessles.

The principal disadvantage of the pressure-contact process in comparison with a conventional double-absorption process is that it consumes more power and produces less steam. The magnitude of this negative effect on operating costs depends on the value of energy.

4.1.4.2. Double-Absorption Processes Based on Metallurgical Gases

Double-absorption plants based on metallurgical gases differ from hot-gas plants based on sulfur combustion in that cold feed gases must first be heated to the converter-inlet temperature using energy liberated in the oxidation of sulfur dioxide.

Process Description. Figure 25 is a flow diagram of a typical double-absorption plant based on metallurgical gases, with a four-bed converter in a (2 + 2) configuration for the production of 98 – 98.5 % sulfuric acid [40]. Sulfur dioxide-containing gases enter the sulfuric acid plant from the gas-cleaning system free of dust and mist but still saturated with moisture. To adjust the O_2/SO_2 volume ratio to the required value of ca. 1.0 – 1.1, air may need to be added to the gas before it enters the dryer. After drying (Section 4.1.3.1), the sulfur dioxide-containing feed gas, at about 50 °C, is compressed by the main blower to a pressure of ca. 1.35 – 1.45 bar, depending on the gas-pressure drop through the plant. The liberated heat of compression raises the gas temperature to ca. 90 – 100 °C.

The sulfur dioxide-containing gases are heated to the converter-inlet temperature of ca. 420 – 450 °C by indirect heat exchange with hot gases from, successively, the fourth, third, and first catalyst beds. Converted gases are simultaneously cooled to the appropriate inlet temperature for the succeeding bed and for the final absorber. In some cases, a boiler element may be installed ahead of the intermediate or final absorber. The converter system and the inter-

Figure 25. Double-absorption sulfuric acid process for metallurgical feed gas (Lurgi)

mediate heat exchangers, as well as the intermediate and final absorption stages, are similar to those in the sulfur-based double-absorption process described previously, except that in this case the intermediate absorption stage is placed after the second catalyst bed rather than the third. Product sulfuric acid of 98 – 98.5 % concentration is withdrawn from the final absorber circuit. If 93 – 97 % sulfuric acid is to be produced, acid discharged from the dryer circuit is preferably stripped with air, which is subsequently used to adjust the O_2/SO_2 ratio of the feed gases. This removes any dissolved sulfur dioxide, reintroducing it into the plant with the feed gas. Most of the water requirement for sulfuric acid production can be satisfied by water vapor absorbed in the gas dryer.

Double-absorption plants of this type are normally designed for contact gases containing 5 – 10 vol % SO_2. Attainable final SO_2 conversions are > 99.5 %. In contrast to cold-gas plants based on pyrite roasting gases, the primary purpose of which is to produce sulfuric acid, sulfuric acid plants associated with nonferrous metal smelters and acid decomposition plants [95–97] have the primary function of cleaning the off-gases. They must therefore be adaptable to frequent large fluctuations in the output and composition of off-gases from the preceding plant. The lower limit for the sulfur dioxide concentration of off-gases subject to processing in a double-absorption plant is determined mainly by two criteria: it must be possible to maintain the water balance, and autothermal operation must be assured. The water balance can generally be maintained with a sulfur dioxide concentration of ca. 3.5 – 4 vol % SO_2 when cooling water at ca. 25 °C is available for the gas cleaning system (see Section 4.1.3.1 and Figure 13).

At the other extreme, modern nonferrous metal smelters generate gases with high SO_2 levels; SO_2 concentrations of up to 10 or 11 vol % may be achieved after mixing/dilution. In such a case the reaction heat developed in the converter system exceeds the requirements for heating the cold gas. The result is an excessively high gas temperature at the entrance to the absorption tower. Boiler elements (economizers, evaporators, superheaters, etc.) are therefore often incorporated into the converter scheme to remove excess heat. A typical flow diagram for such a plant is shown in Figure 26 [180].

Energy Balance. Figure 27 is a Sankey diagram showing the energy balance for a double-absorption plant analogous to Figure 25 based on metallurgical gases. An essential characteristic of a conventional cold-gas plant is that almost all the energy is discharged as waste heat at low temperature. Of the total energy input, 94 % is accounted for as chemical energy released in the conversion of sulfur dioxide to sulfuric acid and in the condensation of water in the dryer. At a feed-gas concentration of 8.5 vol % SO_2 and a dryer inlet temperature of 30 – 40 °C, a total of about 2.7 GJ of thermal energy is liberated per ton of sulfuric acid. This corresponds to a thermal output of ca. 31 MW for a 1000 t/d plant.

About 45 % of the total energy is discharged through the intermediate absorber acid-cooling system, about 23 % through the final absorber acid-cooling system, and about 22 % through the dryer-acid cooling system. In order to maintain autothermal operating conditions, gas-heat losses in the absorption system must be covered by the heat of reaction released in the converter system [40]. At thermal equilibrium, the heat content initially supplied to the converter system during preheating is thus maintained.

For a particular gas throughput, the gas-heat losses remain constant, but the lower the concentration of sulfur dioxide in the feed gas, the less heat is released in the converter system. The lower limit for maintaining thermal equilibrium is about 5 vol % SO_2 for a conventional plant. Minimizing the gas-heat losses in the intermediate absorption stage through the use of venturi-type cocurrent absorbers and the hot absorption principle makes it possible to maintain autothermal operation even when processing contact gases containing as little as 4 vol % SO_2.

Proper design of the gas – gas heat exchangers in relation to the sulfur dioxide concentration is a prerequisite for maintaining thermal equilibrium. The lower the sulfur dioxide content, the smaller will be the difference between the mean inlet and outlet temperatures at each of the catalyst beds. With lower temperature differences, the specific heat-exchanger surfaces must be larger. For example, processing gases with 4 vol % SO_2 rather than 8 vol % SO_2 means that the required specific heat-exchanger surface is more than three times as large [98].

At somewhat higher sulfur dioxide concentrations (8 – 9 vol %), the required specific hea-

Figure 28. Ordinary (single-absorption) contact sulfuric acid plant for metallurgical roaster gas
a) Gas – gas heat exchangers; b) Main blower; c) Drying tower; d) Cooler; e) Acid pump tanks; f) Absorber; g) Converter

texchanger surface reaches a minimum. At still higher sulfur dioxide concentrations it rises again, and in this case it is advisable to install a waste-heat boiler element to convert the surplus reaction heat into steam.

Heat Recovery. In a conventional cold-gas double-absorption plant for processing relatively low-grade sulfur dioxide-containing feed gases, there is no excess high-temperature heat that can be used for generating high-pressure steam (see Fig. 27). However, if the sulfuric acid unit is associated with a fluidized-bed roaster for sulfide ores, high-pressure steam is generally available from a waste-heat boiler system utilizing at least part of the heat of the roasting reaction. In pyrite or zinc blende roasters, for instance, steam is produced at about the same rate per tonne of sulfuric acid as in a double-absorption plant based on sulfur combustion. Where the sulfuric acid plant is linked to a modern smelter (Outokumpu, QSL, Kivcet, etc.), high-level SO_2 gases are available for conversion, so the removal of surplus reaction heat in a waste-heat boiler element becomes almost obligatory. To increase the output of high-pressure steam, low-temperature heat from the absorber-acid circuits can also be utilized for preheating the boiler feed water. Recovery of surplus heat from the acid system, which accounts for ca. 92 % of the entire waste heat produced in a cold-gas plant (see Fig. 27), is of the same economic importance as in a plant based on sulfur combustion. Systems for acid waste-heat utilization have been installed in a number of roaster gas-based double-absorption plants, generating hot water for industrial purposes (e.g., P_2O_5 concentration), or for district heating schemes [99, 100].

4.1.4.3. Ordinary Single-Absorption Processes

Before the introduction of the double-absorption process, the ordinary contact or single-absorption process was the standard sulfuric acid production process [19–23]. Figure 28 is an example of a flow diagram for an ordinary contact plant based on metallurgical gases equipped with a four-bed converter. Before entering the dryer, the cleaned sulfur dioxide-containing gases are generally diluted extensively with air to an O_2/SO_2 volume ratio of at least 1.7. The dried gases are then compressed to

the pressure required to overcome the pressure drop of the overall plant. Although this is about 0.1 bar less than the pressure drop in a comparable double-absorption plant, almost the same specific blower capacity is needed on account of the substantially higher specific gas volume that results from the greater dilution of the feed gas.

The feed gas is heated stepwise in a series of indirect gas – gas heat exchangers cooling first the hot gases from the last catalyst bed and then the gases between the individual beds. The cooled sulfur trioxide-rich gases from the last bed are passed into the SO_3 absorber.

In principle, the ordinary contact process retains more gas heat than the double-absorption processes, because there is no intermediate absorption stage with its associated heat losses. In a roaster-based plant the surplus heat is simply discharged, for instance by indirect air cooling in an air cooler after the third bed (Fig. 28). The reaction heat in a plant based on sulfur combustion is recovered by steam generation in economizers and evaporators. About 10 % more steam is therefore produced per tonne of sulfuric acid in a sulfur-burning ordinary contact plant than in a double-absorption plant of the same capacity [73].

Because of the favorable energy balance, an ordinary contact plant can also process gases with a lower sulfur dioxide content [101]. The lowest sulfur dioxide concentration at which thermal equilibrium can still be maintained in continuous operation without recourse to an external heat source is ca. 2 vol %. The water balance in a sulfuric acid plant based on such a low SO_2 content can be maintained with the aid of a predryer – reconcentrator system developed by Lurgi [51] (see Section 4.1.3.1).

The maximum overall SO_2 conversion attainable in an ordinary contact plant without intermediate sulfur trioxide absorption is 98 –99 % in continuous operation under favorable conditions. Assuming a feed-gas concentration of 7 vol % SO_2, this corresponds to a sulfur dioxide content in the tail gas of about 1600 ppm by volume. Stringent environmental protection regulations introduced since the early 1970s in many industrialized countries demand a higher standard of performance than this. Most new sulfuric acid plants are therefore designed according to the double-absorption principle. Ordinary contact plants are used today only for processing off-gases of extremely low sulfur dioxide content, such as highly dilute smelter off-gases, which cannot sustain autothermal operation in a double-absorption plant. At low feed-gas concentrations (e.g., 3 vol % SO_2) and with the help of highly active (cesium-doped) catalysts, tail-gas SO_2 concentrations are attained that are equivalent to the levels associated with "standard" double absorption plants based on high SO_2 concentrations. In such cases, the ordinary contact process, which produces concentrated sulfuric acid as a marketable end product, is preferable to other off-gas purification methods such as alkaline washing. The SO_2 separation efficiency with these alternative approaches is seldom higher, and they usually lead to unmarketable end products or polluting waste materials.

When necessary, an existing ordinary contact plant can be brought into conformity with strict antipollution legislation either by retrofitting with an intermediate absorption stage, transforming it into a double-absorption plant, or by addition of a tail-gas purification system. Acid waste-heat recovery systems have also been installed in ordinary contact plants [79, 102].

4.1.4.4. Wet-Catalysis Processes

Wet-catalysis processes differ from other contact sulfuric acid processes in that the feed gas still contains moisture when it comes into contact with the catalyst. Sulfur trioxide formed by catalytic oxidation of the sulfur dioxide reacts instantly with the moisture to produce sulfuric acid in the vapor phase to an extent determined by the temperature. Liquid acid is subsequently formed by condensation of the H_2SO_4 vapor and not by the absorption of sulfur trioxide in concentrated sulfuric acid, as in a contact process based on dry gases. The concentration of the product acid depends on the H_2O/SO_3 ratio in the catalytically converted gases as well as on the condensation temperature [103]. The wet-catalysis process is especially suitable for processing the wet, dust-free gases obtained in the combustion of hydrogen sulfide-containing off-gases, which need only be cooled to the converter inlet temperature of ca. 440 °C. Processing these moisture-laden gases in a conventional cold-gas plant would necessitate cooling to an

economically unacceptable extent in order to remove the large excess of moisture, an expedient that would only be justified for a gas with a high dust content and a relatively high sulfur dioxide concentration.

Classical Process. The classical wet-catalysis process was developed by Lurgi as early as the 1930s. It is illustrated schematically in Figure 29. Dust-free hydrogen sulfide-containing gases are burned at ca. 500 – 1000 °C (depending on their composition) with a sufficient excess of air to produce a contact gas with an O_2/SO_2 volume ratio of ca. 1.1 – 1.3. The hot, wet, sulfur dioxide-containing gas is cooled to ca. 440 °C in a waste-heat boiler (or, where the volume of gas involved is very small, in a radiation cooler) and passed directly into the converter. The converter contains three or four catalyst beds, between which cold quench air is added to cool the hot reaction gases.

Gas from the last bed enters a condensation tower at ca. 420 – 430 °C. Here it is cooled to the condensation temperature of sulfuric acid by irrigation with circulated, cooled sulfuric acid. Good contact between the gas and the liquid, as well as a high irrigation density, are essential to ensure that the gas is cooled insofar as possible at the gas – liquid interface of the irrigation acid, causing the condensing sulfuric acid to coalesce with the irrigation acid. This largely avoids formation of the acid mist that would result if sulfuric acid were to condense from the gas phase due to the mixing of cold and hot gas streams. Any mist that does form is subsequently removed from the tail gases by passing them through glass-fiber candle filters. The sulfuric acid thus obtained is fed to the acid circuit of the condensation tower. The gas temperature at the condensation-tower outlet is maintained at ca. 60 °C to restrict H_2SO_4 and SO_3 emission.

Classical wet-catalysis plants are usually designed for the production of 78 % sulfuric acid. Even if the H_2O/SO_3 ratio of the gases leaving the converter were high enough for the product concentration to exceed 78 % (assuming complete condensation of the sulfur trioxide and water), it would not be advisable to operate at higher acid strength because the 80 – 90 % H_2SO_4 concentration range is quite critical with respect to the corrosion-resistance of most of the usual construction materials. The water content of moist hydrogen sulfide-containing gases is normally too high to sustain a sulfuric acid concentration > 90 %.

Acid leaving the condensation tower at ca. 80 – 85 °C is cooled to 50 – 60 °C for recirculation. If necessary, the concentration is adjusted to 78 % H_2SO_4 by addition of process water.

A sulfur dioxide conversion of about 97.5 % is achieved in the wet-catalysis process with a four-bed converter. Since wet-catalysis plants are almost exclusively used for desulfurization of hydrogen sulfide-containing off-gases, the corresponding acid production capacities are comparatively small. The largest wet-catalysis plant built by Lurgi in the United States has a capacity of 250 t/d of H_2SO_4.

The classical wet-catalysis process cannot normally be used for processing wet hydrogen sulfide-containing gases that are too dilute to sustain combustion without supplemental fuel, since the water content of the resulting sulfur dioxide-containing gases would be too high to

permit production of 78 % sulfuric acid. In any case, the opportunities for marketing 78 % sulfuric acid are somewhat limited, and for that reason the wet-catalysis method has been developed further to permit the conversion of gases with extremely low hydrogen sulfide content to sulfuric acid more concentrated than 90 % [104–108]. Examples of such processes are the Concat process (Lurgi) and the WSA process (Haldor Topsoe). Another special development in this area is the wet – dry contact process with intermediate condensation.

Concat Process. Lurgi's Concat process, illustrated schematically in Figure 30, differs from the classical wet-catalysis process principally in the way in which the condensation is accomplished. This occurs in two stages, combining a venturi unit with an irrigated packed tower [103]. In the first stage, the so-called hot condensation, the major part of the sulfur trioxide and/or sulfuric acid condenses at ca. 180 – 230 °C from the hot gases, which leave the converter. At this high condensation temperature only a very small portion of the free water passes from the gas stream into the condensed sulfuric acid on account of the relatively high partial pressure of water vapor over sulfuric acid at this temperature. Therefore, acid with a 93 % H_2SO_4 content can be obtained in the first condensation stage. This section utilizes a venturi scrubber into which the circulating acid is injected in a cocurrent sense relative to the gas to ensure intimate mixing of the gas phase with the liquid phase and the most efficient removal possible of the heat of formation and latent heat of condensation of the sulfuric acid.

As the gas passes between the first and second condensation stages, additional air is injected both for cooling purposes and to reduce the water-vapor partial pressure through dilution. The second stage is a packed tower irrigated with relatively dilute sulfuric acid from which water evaporates as a result of contact with the still moderately hot gas. In the process, the gas is cooled further, and this promotes condensation of the residual sulfuric acid vapor. Gas leaving the condensation tower is freed from remaining acid mists in a candle filter before being discharged to the stack.

Sulfuric acid separated in the candle filter drains into the acid circuit of the condensation tower, from the sump of which excess acid flows over to the hot-condensation stage. Hot acid in the venturi circuit is cooled indirectly. To ensure that it does not exceed the maximum permissible inlet temperature for the particular material of which the cooler is made, part of the cooled acid is recycled to the pump tank. Excess acid that accumulates in the circuit of the first stage is discharged as product after additional cooling.

On account of this two-stage condensation and the cocurrent hot-condensation principle, the Concat process is able to process gas with a sulfur dioxide content of less than 1 vol % and a water content in excess of the stoichiometric requirement, resulting in 78 % or 93 % sulfuric acid. A sulfur dioxide content < 200 ppm can be attained in the tail gas with a two- or three-bed converter depending on the sulfur dioxide concentration of the incoming gases.

Topsoe Wet Sulfuric Acid (WSA) Process [181]. The Topsoe WSA process is used for

treating wet SO_2- containing gases – either "cold gases" (e.g., smelter off-gas) or "hot gases" (from catalytic or thermal incineration units) – without the need for prior drying. The process efficiently recovers sulfur in the form of 93 – 98 % sulfuric acid despite off-gas water contents that may exceed 20 %. Recoveries > 99 % have been achieved. The main components of the process are an SO_2 converter, a heat-exchanger system, and a WSA condenser (see Fig. 31). Upstream from the WSA process, dust and trace materials such as arsenic and hydrogen fluoride are removed by scrubbing if these are present in significant concentrations. Cold gas is heated in two steps. The first heat exchanger uses hot air from the WSA condenser, whereas the second uses the hot converted gases. An in-line burner supplies whatever additional heat is required to reach the appropriate inlet temperature for the SO_2 converter (400 – 420 °C). In cases where the SO_2 concentration exceeds ca. 2.5 %, no supplementary heat is necessary. Surplus heat is used for steam production or dispersed in a cooler.

In the converter, SO_2 is oxidized to SO_3 by means of a sulfuric acid catalyst. Conversion is accomplished either in a single-stage adiabatic converter or in a two-stage converter with intermediate cooling, depending upon the SO_2 concentration and the required level of sulfur removal.

In the next heat exchanger the temperature of the gas is reduced. Cooling causes the SO_3 to react with water in the off-gas to form sulfuric acid vapor. The heat released by this gas-phase hydration is transferred to incoming cold SO_2-containing gases.

Finally, the sulfuric acid vapor is condensed as concentrated acid in the WSA condenser/concentrator, which is an air-cooled glass-tube device. The sulfuric acid-containing gas passes on the tube side and is cooled to ca. 100 °C by ambient air passing on the shell side.

Sulfuric acid condenses selectively and flows downward on the walls of the glass tubes. The acid is concentrated in the lower parts of the tubes by countercurrent contact with hot off-gas; the acid is subsequently collected at the bottom of the condenser. Hot acid leaving the condenser is cooled in a water-cooled plate cooler before being pumped to a storage tank.

Careful control of the temperature and of sulfuric acid droplet formation makes it possible to keep the level of sulfuric acid in the cleaned off-gas low without the use of any subsequent wet electrostatic precipitator or low-velocity mechanical filter. Cleaned off-gas leaves the top of the condenser and goes to a stack. Cooling air leaves the condenser at ca. 200 °C, and is used for preheating the cold feed gas.

In power-plant boiler applications the WSA process is combined with a selective catalytic reduction (SCR) NO_x removal system. The first heat-exchanger step is omitted, because the off-gas is already hot as received after dust filtration. A rotary gas – gas heat exchanger is used to heat the off-gas ahead of the SO_2 converter. The SO_2 converter is an adiabatic dust-tolerant type with a number of vertical catalyst beds placed in parallel array. The catalyst beds can be dedusted one by one while the SO_2 converter remains online without disrupting plant operation. Hot cooling air from the WSA condenser is used as boiler combustion air.

The main construction material employed in the WSA system is either carbon steel or low-alloy steel.

Wet – Dry Contact Process. The wet – dry contact process with intermediate condensation, a joint development by Lurgi and Süd-Chemie, is a modified double-absorption process based on sulfur combustion. Instead of dried air, industrial waste air contaminated with such sulfur compounds as hydrogen sulfide, carbon disulfide, or carbonyl sulfide is used to burn the sulfur [109]. The impurities are oxidized simultaneously with combustion of the sulfur. The resultant gases, containing 9.5 – 10 vol % SO_2 and less than the stoichiometric amount of water necessary for the formation of 98.5 % sulfuric acid, are passed into the converter after prior cooling in a waste-heat boiler (Fig. 32).

In contrast to the normal double-absorption process based on sulfur combustion, the moist

Figure 32. Wet/dry catalysis sulfuric acid plant with intermediate condensation/absorption

sulfur trioxide-containing gases formed in the first beds of a wet-catalysis system are passed on to a two-stage intermediate condenser. In the first stage, which is a vertical venturi unit, the entire water content of the gas and most of the sulfur trioxide are removed into hot sulfuric acid injected cocurrently. Remaining sulfur trioxide is absorbed in the second stage, a packed tower irrigated with cold acid. The concentration of the circulating acid is adjusted to 98.5 % by the addition of process water. Dry SO_2- containing residual gases from the intermediate condenser are processed in the same way as in a normal double-absorption plant (Section 4.1.4.1).

A plant of this type for the production of 120 t/d of sulfuric acid has been in operation at the Kelheim works of Süd-Chemie since 1980. This plant processes off-gases from a rayon staple factory containing ca. 0.5 vol % $H_2S + CS_2$ [109, 110].

4.1.5. Tail-Gas Treatment

The tail gases from a sulfuric acid contact plant consist chiefly of nitrogen and residual oxygen. They also contain sulfur dioxide at a low concentration that depends on the conversion efficiency attained in the conversion stages. The content of gaseous sulfur trioxide and sulfuric acid is essentially a function of the temperature and concentration of irrigation acid in the final absorber. Under unfavorable operating conditions (e.g., when the sulfur dioxide-containing converter feed gases are inadequately dried, or contain hydrocarbons) sulfuric acid mists may form which are not removed in the absorption system. This is true even when the concentration and temperature of the absorber acid are at their optimum values. The safest way to remove these acid mists is with a candle filter, although this is not very effective for removing excess sulfur trioxide, which may result from poor acid distribution in the absorber.

The sulfur dioxide level in the tail gases is dependent not only on the sulfur dioxide conversion achieved but also on the SO_2 content of the converter feed gases (Fig. 33). However, the specific sulfur dioxide emission rate (kilograms of SO_2 per tonne of 100 % H_2SO_4) is a function only of the sulfur dioxide conversion efficiency.

An essential prerequisite for attaining maximum sulfur dioxide conversion and correspondingly low sulfur dioxide emission is maintaining the gas conditions at the converter inlet (gas volume, gas temperature, sulfur dioxide concentration, and O_2/SO_2 ratio) as constant as possible. This is in general reasonably easy in a sulfuric acid plant based on sulfur combustion or metallurgical gases from a fluidized-bed furnace. But in sulfuric acid plants associated with metal smelters, especially copper smelters incorporating converter operations (→ Sulfur Dioxide, Chap. 5.5.1.), wide fluctuations in the gas-flow rate as well as in the off-gas sulfur dioxide concentration are quite normal [111, 112]. Consequently, the sulfur dioxide content of tail gases from the corresponding sulfuric acid plants themselves may vary quite noticeably from the optimum value. It is also almost impossible in most cases to avoid fluctuating emissions during start-up [113].

Figure 33. Sulfur dioxide emission as a function of SO_2 concentration at the converter inlet and the SO_2 conversion rate

Replacing the normal contact process by a double-absorption process results in a marked reduction in sulfur dioxide emissions [114–116]. The specific sulfur dioxide emission of a single-

absorption plant with a sulfur dioxide conversion of 97.5 % is about 17 kg of SO_2 per ton of H_2SO_4. Corresponding values for double-absorption plants with sulfur dioxide conversion efficiencies of 99.5 % and 99.7 % are ca. 3.3 kg and 2 kg of SO_2 per tonne of H_2SO_4 respectively (Fig. 33). For a plant with an H_2SO_4 capacity of 1000 t/d this translates into a reduction from 710 kg/h of SO_2 to ca. 138 kg/h or 83 kg/h. Theoretically, it would be possible to improve the conversion efficiency, and thus reduce emissions still further, by introducing an additional intermediate absorption stage, corresponding to a triple-absorption process. In practice, however, this method is not feasible, for both technical and economic reasons [80].

Environmental regulations – in Germany, for example – call for further improvement in the conversion efficiency normally achieved with a double-catalysis plant. At locations where the maximum permissible ground-level SO_2 concentration is exceeded because of emissions from other nearby sources, it may even become necessary to reduce SO_2 emissions below the value attainable with a conventional double-absorption process. Two approaches to a further reduction of the SO_2 emissions might be considered in such cases: installation of a fifth catalyst bed, or addition of a tail-gas treatment unit. Whereas the SO_2 reduction in a 5-bed converter system is achieved through an improvement in conversion efficiency, reduction of SO_2 emissions in a tail-gas treatment plant is effected by reacting the SO_2 with some type of scrubbing liquor. The 5-bed converter system will probably continue to be the most convenient solution for new plants so long as the target conversion efficiency remains at approximately 99.8 %. In the case of an existing plant, "add-on" tail-gas treatment may be feasible, although some processes of this type lead to byproducts that also require treatment. Of the known tail-gas cleaning processes, ammonia washing, the Wellman – Lord process, and the Sulfacid process are most suitable for application in normal contact plants; the Peracidox process is used only in conjunction with double-absorption plants. For a single catalysis plant, upgrading to a double-absorption operation remains an attractive alternative to a tail-gas scrubbing system.

Ammonia Washing. Sulfuric acid tail-gas purification processes based on ammonia washing are distinguished mainly by the method selected for reprocessing the sulfur dioxide-laden scrubbing liquor [111, 115–120]. Figure 34 shows a Lurgi-designed system capable of removing up to 95 % of the incoming sulfur dioxide. This high level of sulfur dioxide removal is made possible by a two-stage gas-scrubbing system.

Tail-gases from the absorber of the sulfuric acid plant are washed with circulated ammonia solution in two venturi scrubbers arranged in series. Unconverted sulfur dioxide in the tail gas dissolves as ammonium sulfite or ammoni-

Figure 34. Ammonia scrubbing system for an ordinary (single-absorption) contact sulfuric acid plant
a) Ammonia scrubbers; b) Gas filter; c) Decomposer; d) Fan; e) Stripper

um hydrogensulfite. Any sulfur trioxide or sulfuric acid carried over from the absorber is transformed into ammonium sulfate or ammonium hydrogensulfate. Before being discharged to the stack, the cleaned gas is passed through a mist eliminator. Liquor drawn from the mist eliminator and fresh ammonia solution are then introduced into the second venturi srubber. Scrubbing solution from the second stage overflows to the first. Thus, the solution in the second stage, where the sulfur dioxide content of the tail gas is lower than in the first, has a higher pH and a lower sulfite concentration than the solution in the first stage, causing the partial pressure of sulfur dioxide to be reduced even further in this stage.

A bleed stream of sulfite-rich scrubbing solution is withdrawn from the first stage and introduced into a decomposer along with concentrated sulfuric acid. The acid decomposes the sulfites, liberating sulfur dioxide and forming an ammonium sulfate solution. This solution retains a certain amount of dissolved sulfur dioxide, which is subsequently stripped out with air. Moist sulfur dioxide gas from the decomposer is combined with the stripping air and recycled to the dryer of the sulfuric acid plant.

The economics of an ammonia tail-gas scrubbing process depend chiefly on the fate of ammonium sulfate solution discharged from the stripper [118–120]. The most favorable situation is one in which the sulfuric acid plant is part of a fertilizer complex, because in that case the solution can probably be used directly in the production of granular fertilizers, and ammonia is likely to be available at a reasonable cost. Otherwise, assuming there is an adequate market, the ammonium sulfate may be sold, so that at least part of the ammonia cost can be recovered through a credit for the ammonium sulfate. Normally, however, there is little prospect for selling the solution directly, and working it up into solid products would involve additional capital investment as well as energy, leading to high operating costs.

In a sulfuric acid plant designed to regenerate spent acid (→ Sulfur Dioxide, Chap. 5.6.1.), sulfite solution formed in an ammonia tail-gas scrubbing system can be disposed of in the spent-acid decomposition furnace. This circumvents the problem of finding an outlet for byproducts, but the resulting convenience must be paid for in lost ammonia values, since ammonia is oxidized to nitrogen. Also, decomposition of the sulfite solution and especially the evaporation of water require additional energy, which is not matched by the heating value of the ammonia that is burned.

Wellman – Lord Process. In the Wellman – Lord process, sulfur dioxide is washed from the acid-plant tail gas by a saturated aqueous solution of sodium sulfite and sodium hydrogensulfite (→ Sulfur Dioxide). Wet sulfur dioxide-containing gas expelled during thermal regeneration of the scrubbing solution is recycled to the contact plant. About 10 – 20 % of the recovered sulfur ends up as sodium sulfate owing to oxidation to sulfite in solution. This dissolved sodium sulfate cannot be decomposed, so it must be removed as a byproduct. The economics of the process are determined by the purity and marketability of the byproduct.

Sulfacid Process. The Sulfacid process is a tail-gas purification method (developed by Lurgi) that produces dilute sulfuric acid as a byproduct [111, 115, 121, 122]. Dry tail gas normally leaves the sulfur trioxide absorber of an acid plant at 75 – 80 °C. This is first humidified with steam and then passed through a reactor filled with activated carbon. Sulfur dioxide adsorbed by the wet activated carbon is oxidized to sulfuric acid at 50 – 80 °C by residual oxygen in the tail gas. This acid, together with traces of sulfur trioxide and sulfuric acid removed from the tail gas, is retained in the pores of the carbon. The purified gas is discharged to the stack at 40 – 80 °C; the attainable sulfur dioxide separation efficiency is normally > 90 % [121]. Adsorbed acid is washed out by spraying the activated carbon bed with water at regular intervals without interrupting the gas flow.

The concentration of acid discharged from the reactor is kept below 20 – 25 % in an industrial plant by the dilution effect of the flushing water. Increasing the acid concentration by decreasing the water flow-rate would reduce the solubility of sulfur dioxide and, consequently, the sulfur dioxide-removal efficiency. The resulting dilute acid is recycled to the contact plant, where it takes the place of process water.

If the amount of water introduced with the dilute acid exceeds the water requirements of

the contact plant, the dilute acid may be concentrated by means of the well-established venturi method (see also page 53). In this case acid leaving the Sulfacid reactor is passed on to a single- or double-stage venturi reconcentrator located upstream from the Sulfacid reactor. In the course of raising the acid concentration above 30 % the tail gas itself will absorb enough water vapor from the acid to render the humidification stage of the basic process unnecessary, with a consequent saving in steam. Furthermore, the tail-gas heat is utilized in concentrating the acid. Any additional heat required can be supplied by indirect heat exchange between the acid-plant absorber and the concentrator [122].

Peracidox Process. The Peracidox process is an oxidative sulfur dioxide-removal process developed by Lurgi and Süd-Chemie [121, 123] for purifying the already very dilute tail gas from a double-absorption sulfuric acid plant. It does not lead to any byproducts or waste, producing only sulfuric acid, which is recycled to the main sulfuric acid plant.

Hydrogen peroxide or electrolytically produced monoperoxysulfuric acid (H_2SO_5) is used to oxidize sulfur dioxide to sulfuric acid [55, 122]:

$$SO_2 + H_2O_2 \longrightarrow H_2SO_4 \tag{14}$$

$$SO_2 + H_2SO_5 + H_2O \longrightarrow 2\,H_2SO_4 \tag{15}$$

Figure 35 is a flow diagram of the electrolytic version of the Peracidox process. Tail gas leaving the final absorber of the sulfuric acid plant is washed in a two-stage Peracidox scrubber with ca. 30 – 40 % sulfuric acid in which the oxidant is dissolved. The attainable sulfur dioxide-removal efficiency is > 90 %. Entrained sulfuric acid vapor and residual sulfur trioxide are washed out simultaneously.

The oxidant is generated in an electrolytic unit by oxidizing H_2SO_4 anodically in a dilute sulfuric acid stream produced from concentrated acid from the product line. Diperoxysulfuric acid ($H_2S_2O_8$) initially formed in the electrolytic cell disproportionates in the dilute acid to form sulfuric acid and monoperoxysulfuric acid (Caro's acid) as the final oxidizing agent. When hydrogen peroxide is used as the oxidant, the electrolysis unit and pump tank are not, of course, required – only a storage tank for the hydrogen peroxide [55].

Oxidizing solution is introduced into the acid circuit of the second scrubbing stage at a stoichiometric rate proportional to the amount of sulfur dioxide to be removed. Any residual oxidant in solution overflowing to the first scrubbing stage reacts there with the entering tail gases. Overflow withdrawn from the circuit of the first stage thus consists only of dilute sulfuric acid, and it is introduced into the final or intermediate absorber of the main acid plant in place of process water.

Depending on the location of the plant and prevailing prices for electric power or hydrogen peroxide, the operating costs for a Peracidox process with electrolytically produced oxidant may be lower than costs incurred with the use of hydrogen peroxide [55]. If tail-gas purification is required only intermittently during short periods when sulfur dioxide emissions temporarily exceed permitted limits – during start-up, for example – it is more economical to use hydrogen peroxide on account of the lower investment costs [122].

Figure 35. Lurgi Peracidox tail-gas purification system (electrolytic version)
a) H_2SO_4 plant final absorber; b) Cooler; c) Pump tank; d) Peracidox scrubber; e) Electrolytic oxidation unit; f) Electrolyte tank

A Peracidox tail-gas scrubbing unit with electrolysis has been in operation since 1972 at a 120-t/d double-absorption sulfuric acid plant in Germany [123]. Another scrubbing unit, using hydrogen peroxide and attached to a 330-t/d double-absorption sulfuric acid plant (also in Germany) has been operating since 1982 [124].

4.1.6. Economic Factors

Economies of Scale. Due to a steep increase in demand for sulfuric acid since the early 1950s, the unit size of sulfuric acid plants has been constantly increasing. For example, in 1954 the largest sulfuric acid plants in the Federal Republic of Germany were designed for production of ca. 250 t/d, and in the United States for about 450 t/d. Today, the largest double-absorption plants have capacities of ca. 1000 t/d in the Federal Republic of Germany and ca. 3000 t/d in the United States.

The incentive for steadily increasing the size of sulfuric acid production units is "economy of scale" – savings achieved in both specific capital and production costs. This is particularly important in view of the opposing effect of increasingly stringent environmental protection regulations. The measures required for conforming with these restrictions inevitably increase the complexity of the plant, introducing energy and capital cost penalties.

Economics of Voluntary Production. The relationship between specific capital cost and unit production capacity can be seen from Figure 36 for a sulfur-burning double-absorption sulfuric acid plant. The production of sulfuric acid from elemental sulfur represents the most economical and flexible option with respect not only to capital costs but also operating expenditure (utilities, manpower, absence of byproducts apart from steam). As a general rule, the sulfuric acid production costs in a large plant are determined chiefly by the raw materials, which means the price of sulfur, since the credit for steam production usually covers all other costs (such as electric power, cooling water, labor, depreciation, interest, administration, and maintenance).

In contrast, a sulfuric acid plant based on the roasting of pyrite is not only about twice as expensive to build (if the cost of the roasting and gas-cleaning systems are included) but also uses about twice as much electric power and about twice as much manpower as a sulfur-burning plant. Nonetheless, in cases involving domestic pyrite deposits that are economical to exploit for their nonferrous metals content, pyrite often represents a cheaper raw material source for sulfuric acid manufacture than expensive imported sulfur.

Figure 36. Relationship between specific capital cost and production capacity for a sulfur-burning double-absorption sulfuric acid plant

Without assigning a credit value for the cinder, the cost of producing sulfuric acid from pyrite is roughly comparable to that of producing it from elemental sulfur if the sulfur content of the pyrite costs ca. 25 % less than elemental sulfur. Depending on its chemical composition and prevailing market conditions, the byproduct cinder may exert either a positive or a negative influence on total costs. If the cinder can be utilized in a nearby cement fatory, for example, the credit may cover up to 15 % of the pyrite costs. In the least favorable case, the cost of removing and disposing of the cinder might constitute an additional burden on sulfuric acid production costs.

Economics of Involuntary ("Fatal Acid") Production. In any economic feasibility study, sulfuric acid obtained in the processing of metallurgical off-gases as a compulsory byproduct of a nonferrous-metal smelter operation (e.g., copper, nickel, zinc, lead, or molybdenum) must be valued differently from sulfuric acid of the same quality produced as a primary product in a plant based on sulfur combustion or pyrite roasting [125].

Sulfuric acid plants based on metallurgical off-gases are essentially pollution control plants, and they must operate in accordance with the production requirements of the accompanying smelter complex. Under such conditions it is not appropriate to expect the sulfuric acid plant to operate profitably, merely that proceeds from the sale of sulfuric acid should, if possible, cover the off-gas desulfurization costs. The capital costs of such a plant (including the wet gas-cleaning system as well as the sulfuric acid plant proper) depend heavily on the sulfur dioxide concentration of the gases to be processed (Fig. 37 A) [40].

Figure 37. Capital cost (A) and operating cost (B) for a double-absorption sulfuric acid plant and wet gas - cleaning system as a function of feed gas sulfur dioxide concentration a) Total; b) Sulfuric acid plant; c) Wet gas - cleaning system

If the sulfur dioxide concentration and the gas volume of the off-gas stream are subject to frequent wide fluctuations, the capital cost for the gas-cleaning system and the sulfuric acid plant may approach that for a complete pyrite plant with a comparable acid capacity.

The current price disadvantage in the marketing of large quantities of sulfuric acid as a compulsory product (which frequently reflects a substantial freight cost owing to unfavorable location of the production facility, in relation to the market) is compensated by the fact that the sulfur dioxide content of the smelter off-gases is charged at zero cost in the cost calculation. However, in contrast to sulfur-burning and pyrite-based plants, there is no steam credit in a metallurgical sulfuric acid plant unless high-grade sulfur dioxide-containing smelter off-gases can be anticipated in the future [57].

The gas-processing costs and specific operating costs show a dependence on the feed-gas sulfur dioxide concentration similar to the capital costs, since capital-dependent costs account for most of the processing costs (Fig. 37 B).

4.2. Production by Nitrogen Oxide Processes

In a nitrogen oxide process, sulfur dioxide is oxidized to sulfuric acid in an aqueous phase, with nitrogen oxides serving as oxygen carriers. Processes of this type include the lead chamber processes (e.g., Mills – Packard and Gaillard) and the tower processes (e.g., Curtius, Petersen, Kachkaroff, Matignon, Salsasserra, and Moritz). These processes formerly constituted the basis for sulfuric acid production [19–23], but they have now been replaced almost completely by the modern contact processes (see Chap. 3). Nevertheless, nitrogen oxide processes are of interest not only from the point of view of the history of chemical theory, technology, and industrial practice, but also because they have certain characteristics that may qualify them for use even today (in an improved design adapted to specific cases), despite certain general disadvantages relative to contact processes.

Chemistry. Nitrogen oxide processes are based on oxidation of sulfur dioxide in the liquid phase. The detailed reaction mechanism is not fully understood even today, though this is one of the oldest industrially applied processes. In a simplified form, the course of reaction can be described by the following equations:

$$SO_2 + 2NOHSO_4 + 2H_2O \longrightarrow 3H_2SO_4 + 2NO \quad (16)$$
$$NO + 1/2\,O_2 \longrightarrow NO_2 \quad (17)$$
$$NO_2 + NO \rightleftharpoons N_2O_3 \quad (18)$$
$$N_2O_3 + 2H_2SO_4 \rightleftharpoons 2NOHSO_4 + H_2O \quad (19)$$
$$SO_2 + 1/2\,O_2 + H_2O \longrightarrow H_2SO_4 \quad (20)$$

Sulfur dioxide absorbed in the aqueous phase is actually oxidized by nitrosyl hydrogensulfate, $NOHSO_4$ ("nitrosylsulfuric acid"), dissolved in ca. 70 % sulfuric acid ("nitroso acid"), yielding sulfuric acid and releasing gaseous nitric oxide, NO. The colorless nitric oxide, which is virtually insoluble in aqueous systems, is oxidized by free oxygen in the gas stream to form the yellow nitrogen dioxide, NO_2. Nitric oxide and nitrogen dioxide are in equilibrium with the relatively unstable nitrogen sesquioxide, N_2O_3, which to some extent dissolves in sulfuric acid.

In sulfuric acid of greater than 70 % strength, nitrogen sesquioxide reacts to form nitrosyl hydrogensulfate, which is a relatively stable compound at higher sulfuric acid concentrations. In ca. 70 % sulfuric acid, however, nitrosyl hydrogensulfate is metastable and behaves as a very reactive oxidant toward sulfur dioxide. For this reason it is not possible to produce sulfuric acid of significantly higher concentration without accepting a higher residual nitrogen oxide content.

Application as a Pollution Control Process. The low concentration of the product acid, which (for reasons explained above) cannot economically exceed ca. 78 %, constitutes the overriding disadvantage of any nitrogen oxides process. Sulfuric acid of this concentration has relatively few applications today. It is not economical to concentrate it because of the high energy costs involved. Viewed strictly as a method of manufacturing sulfuric acid, therefore, the nitrogen oxides process is no longer competitive with contact processes. It has the further disadvantage that none of the heat released is at a sufficiently high temperature to permit its economical recovery.

On the other hand, the low working temperatures of the nitrogen oxide process offer certain advantages in specific cases. Thus, it is suitable for processing gases with extremely low sulfur dioxide contents, which cannot be converted in a contact plant without supplementary heating. The nitrogen oxide process has also been proposed by Tyco as a method for removing both sulfur and nitrogen oxides from flue gases [126].

Ciba – Geigy Process. Since 1974, Ciba – Geigy has been developing a nitrogen oxide sulfuric acid process specifically designed for the processing of gases containing ca. 0.5 – 3 vol % SO_2 and offering special advantages when the gases are laden with nitrogen oxides [127].

A flow diagram of the Ciba – Geigy nitrogen oxide process is shown in Figure 38. The

Figure 38. Ciba – Geigy nitrogen oxide sulfuric acid process
a) Venturi scrubber; b) Star cooler; c) Product acid denitrator; d) Gas dryer; e) Cooler; f) Blower; g) Denitration tower; h) SO_2 oxidation reactors; i) Nitrogen oxide absorbers; j) Concentrator

sulfur dioxide-containing gases are first passed through a wet gas-cleaning and cooling system to remove dust and reduce the water-vapor content. In a subsequent gas dryer, surplus moisture is absorbed in 50 – 60 % sulfuric acid and transferred via the outer acid loop to a concentrator, where it is evaporated into the tail gases. In principle, this is quite comparable to the Lurgi predryer – reconcentrator system used to maintain the water balance in a contact-process acid plant (see page 15).

The product *denitrator* serves as a final nitrogen oxides stripping stage for the product-acid bleed stream. Nitrogen oxides are removed from the irrigation acid partly by reaction with sulfur dioxide (reaction 16) and partly by hydrolysis (the reverse of reaction 19). Sulfuric acid leaving the tower is free of nitrogen oxides, and has a concentration of 70 – 80 %, preferably 78 % (60° Bé). Part of the sulfur dioxide feed already has been removed when the gases pass on to the denitrator.

In the denitrator up to ca. 50 % of the sulfur dioxide feed is oxidized by nitrosyl hydrogensulfate present in recycled acid from the first nitrogen oxide absorber. Nitric oxide is released into the gas stream. The incoming acid is heated in a recuperative acid heat exchanger, while acid leaving the denitrator is cooled before being recycled to the second nitrogen oxide absorber.

The two sulfur dioxide reactors serve to reoxidize nitric oxide and remove remaining sulfur dioxide. The transformation of sulfur dioxide into sulfuric acid takes place at the extensive gas – liquid interface presented in the irrigated reactor towers by packings of a special design. Reaction heat from the oxidation of sulfur dioxide is removed by cooling the circulating acid.

In the two nitrogen oxide absorbers, nitrosyl hydrogensulfate is formed by the reaction of nitrogen oxides present in the gases with sulfuric acid recycled from the denitrator via the inner acid loop. The gas and the irrigation acid flow cocurrently in the first absorption tower and in countercurrent fashion in the second. Acid discharged from the second tower is pumped to the preceding nitrogen oxide absorption tower after cooling.

Efficient absorption of the nitrogen oxides depends not only on adequate cooling of the irrigation acids but also on precise control of the NO/NO_2 ratio, which is monitored continuously at the outlet of the nitrogen oxide absorption stage by automatic analyzers. To ensure maximum nitrogen oxide absorption, the plant is designed and operated such that gases entering the absorption towers contain nitric oxide and nitrogen dioxide in almost equimolar quantities, which favors the formation of nitrogen sesquioxide. Nitric oxide in excess is scarcely absorbed at all. On the other hand, nitrogen dioxide in excess does dissolve to some extent, but it is partly converted back into insoluble nitric oxide. Some autoxidation of nitric oxide to nitrogen dioxide takes place in the absorption towers, though this is a slow reaction.

Sulfur dioxide remaining in the gas at the nitrogen oxide absorption stage will again liberate nitric oxide. A high sulfur dioxide content in the entering gases therefore causes a disproportionate rise in nitric oxide losses to the tail gases. Consequently, a high sulfur dioxide conversion efficiency in the sulfur dioxide reaction step is prerequisite to minimizing nitrogen oxide concentrations in the tail gases. The final sulfur dioxide content is actually lower than 100 ppm by volume.

Up to ca. 1 g/m^3 of nitric oxide and nitrogen dioxide may remain in the tail gas, but this is not the only cause of nitrogen oxide loss in the overall plant. Side reactions also take place in which nitrogen oxides are converted to such species as nitrous oxide, N_2O, and elemental nitrogen, while a certain amount of nitrosyl hydrogensulfate is discharged with the product acid.

Nitrogen losses must be compensated by the addition of nitric acid to the sulfur dioxide reactors in order to maintain the nitrogen oxide balance in the entire system. Another possibility is the addition of nitrogen oxides generated by burning ammonia. If the sulfur dioxide-containing feed gases already contain nitrogen oxides, the stoichiometric equivalent of nitric acid or ammonia can be saved.

The first commercial plant based on the Ciba – Geigy nitrogen oxides process has been in operation near Goslar (Federal Republic of Germany) since 1979. It is designed to desulfurize 10 000 m^3/h of off-gases containing ca. 0.8 – 1.5 % SO_2 from a molybdenum sulfide roasting unit. A characteristic of this plant is the almost exclusive use of plastics as construction materials. In comparison with earlier tower plants, the specific reaction-space requirements (in relation

to gas throughput) have been substantially reduced. An elaborate automatic measuring and control system restricts nitrogen oxide emissions to a minimum.

4.3. Regeneration of Spent Sulfuric Acid

4.3.1. Introduction

Most of the sulfuric acid produced enters not into marketable end products, but instead ends up as spent acid, impure gypsum, or other metal sulfates, all of which are waste products. Disposal of these chemical wastes represents an unsolved environmental problem that is becoming more serious as production capacities expand and antipollution regulations become more stringent.

The bulk of the spent acid is generated by the organic chemical and petrochemical industries. The nature of the acid varies widely from highly dilute to relatively concentrated, and with both low and high levels of organic and inorganic impurities. Large volumes of uniform spent acid arise only in the course of plastics production (e.g., methacrylate, caprolactam); typical data related to the quantity and composition of representative spent acids are as follows:

Composition figures for alkylation acid:	
Sulfuric acid content	ca. 88 – 90 %
Water content	ca. 5 %
Organics	ca. 3 – 4 %
Organic sulfates	ca. 2 %

Production and consumption figures for caprolactam manufacture:	
Caprolactam production rate	120 000 t/a
H_2SO_4 consumption (100 % acid)	636 kg/t of caprolactam
Oleum consumption	1 300 kg/t of caprolactam
Ammonium sulfate production	312 000 t/a (including spent acid)
Spent acid composition:	
Sulfuric acid	ca. 50 %
Salt content	ca. 0.7 %
Water	balance

Production and consumption figures for methyl methacrylate (MMA) manufacture:	
Methyl methacrylate production	50 000 t/a
H_2SO_4 consumption (100 % acid)	1.8 t per tonne of MMA
Spent acid production	2.7 t per tonne of MMA
Spent acid composition:	
Sulfuric acid	ca. 20 %
Ammonium hydrogensulfate	ca. 45 %
Water	ca. 30 %
Organics	ca. 5 %
Solids	ca. 2 %

An important source of spent acids containing inorganic impurities is the inorganic chemicals industry, especially the TiO_2 pigment industry, which generates spent acid of a relatively uniform quality containing ca. 20 – 23 % H_2SO_4 and 7 – 15 % metal sulfates. Similar in quality is the spent acid obtained from pickling operations in the metallurgical industry. Another source of waste acid is the gas-cleaning section of a roasting or other "metallurgical" acid plant.

A typical analysis of spent acid obtained from TiO_2-pigment manufacture is as follows:

Sulfuric acid	22 %
Iron sulfate	4.5 %
Calcium sulfate	0.1 %
Other metal sulfates	5.4 %
Water	68 %

In the past, typical methods of disposal or recycling for spent sulfuric acids included

1) Neutralization with lime
2) "Ocean dumping"
3) Reconcentration/blending with oleum

Stricter pollution-control regulations together with more limited disposal areas have now virtually eliminated the use of such neutralization and dumping methods in the industrialized countries. Reconcentration of weak acids by blending with oleum also has its practical limits. Indeed, the method is suitable only for small acid volumes involving high H_2SO_4 concentrations, and even then only if the specific impurity content is such as to permit recycling or use of the acid in some other process.

Regeneration of spent sulfuric acids is therefore the only method available for obtaining a product of original quality and at the same time complying with environmental regulations, although the cost of acid derived from such a process greatly exceeds the production cost in a "normal" sulfuric acid production plant.

The regeneration of spent acid normally comprises two major process steps:

1) Concentration of the spent acid to the highest feasible level, together with separation of salts to the extent necessary
2) Decomposition of the spent acid and/or sulfates

No single procedure can be considered universally suitable for concentrating all types of

spent sulfuric acid. The choice of an evaporation method also depends on the extent to which the specific application for which the regenerated sulfuric acid is ultimately destined is able to tolerate residual impurities.

The process of concentrating of dilute sulfuric acid consumes substantial amounts of heat energy, not only to evaporate water but also for dehydrating the acid (see Section 2.1). For concentration at atmospheric pressure at or near the boiling point it must also be borne in mind that the boiling point of sulfuric acid rises steeply as the H_2SO_4 concentration increases.

The combination of high acid temperature, intermediate H_2SO_4 concentrations, and certain types of impurities can give rise to extremely corrosive conditions, necessitating the use of special construction materials for the concentration equipment.

Spent sulfuric acid can be concentrated by direct or indirect heating, and in one or several stages. The methods can be classified into two large groups [128]:

1) Evaporation to an H_2SO_4 concentration $\leq$ ca. 75 wt %
2) Evaporation to high concentration (up to the azeotropic point, 98.3 % H_2SO_4 at atmospheric pressure)

In concentrating to less than 75 % H_2SO_4, water is almost the only substance evaporated. The H_2SO_4 content of the gas phase is negligible on account of the low H_2SO_4 vapor pressure (see Section 2.1), so a scrubbing system for removing sulfuric acid is seldom necessary. Evaporating to a higher concentration (up to the azeotropic point) requires a relatively high temperature. However, the specific evaporation-heat requirement in the higher concentration range is relatively low because little water remains. For example, if spent acid containing 20 % H_2SO_4 is concentrated to 98 % in two stages – from 20 % to 75 % and then from 75 % to 98 % – ca. 92 % of the total amount of water removed evaporates in the first step, leaving only 8 % to be evaporated in the second.

A more detailed description of the various approaches to reconcentration is presented in Section 4.3.2.

The second and more fundamental regeneration step is decomposition of the spent acid and/or sulfates. Such sulfates may be present in the acid itself (e.g., as ammonium hydrogensulfate) or they might be isolated in the form of free metal sulfates (e.g., $FeSO_4 \cdot H_2O$ from TiO_2-pigment spent acid). The selection of an appropriate decomposition procedure is crucial for satisfactory operation, where the composition of the acid and the solids/salts content are the determining factors. Three process concepts that have proven their worth in industrial-scale applications are:

1) Gas-phase decomposition in an empty decomposition furnace
2) Decomposition above a red-hot coke bed in a rotary kiln (Grillo process)
3) Decomposition in a fluidized bed

For more detailed descriptions of the various decomposition processes, see → Sulfur Dioxide, Chap. 5.6.2.

A decomposition plant of this type is normally found in conjunction with a gas-cleaning plant and a sulfuric acid contact plant, such that the final product is pure sulfuric acid.

The spent-acid regeneration plant realized in Sachtleben Chemie is outlined in Fig. 39 [182]. It represents an integrated regeneration process for spent acid from a TiO_2-pigment fabrication process.

Spent acid as received from the TiO_2 production facility is first concentrated from ca. 22 % H_2SO_4 to ca. 70 % in a vacuum concentration plant. The 70 % $H_2SO_4/FeSO_4$ suspension is then passed through the "maturation station," representing the 2nd stage of the process. After maturation the suspension passes through a filter plant separating the acid from the sulfates (stage 3). The sulfates recovered from the filter are prepared for decomposition, mixed with pyrite and carbon, and passed to an intermediate storage facility (stage 4). The filtrate (sulfuric acid with 70 % H_2SO_4) is further concentrated to ca. 80 % H_2SO_4 in another vacuum concentration plant (stage 5). The acid that results is ready for immediate use in the TiO_2 attack section. In stage 6, the mixture of sulfate/carbon/pyrite from stage 4 is fed into a fluidized-bed roaster for decomposition. The SO_2 gas is cooled, cleaned, and transformed into sulfuric acid in a contact acid plant.

Figure 39. Integrated spent-acid regeneration process

4.3.2. Reconcentration to 70 – 75 % H_2SO_4

Vacuum Evaporation. In this process, dilute sulfuric acid is maintained at the boiling temperature under vacuum by indirect heating with steam. The vapors evolved are recondensed almost completely in a downstream cooling system so that, apart from insignificant amounts of inert gases desorbed from the acid, there is no gaseous effluent. Other dissolved volatile impurities that may be present, especially in organic-contaminated acids, can generally be condensed as well. Heavily contaminated acids containing inorganic substances, which tend to deposit solids during evaporation, are effectively concentrated in forced-circulation evaporators, whereas for comparatively pure spent acids a natural circulation system may be adequate [128]. Evaporators of this type are satisfactory for concentrating dilute sulfuric acid to 70 – 80 % [129].

Forced-Circulation Evaporator. In the forced-circulation evaporator shown in Figure 40, the heater is separate from the flash vessel. With this arrangement it is possible to prevent evaporation in the heater itself, so solids deposition on the heating surfaces is kept to a minimum. An additional advantage of forced circulation over natural circulation is that the liquid-flow velocity in the heat exchanger is

higher and more easily controlled; as a result, the heat-transfer conditions are more stable.

Figure 40. Forced-circulation evaporator with separate heater
a) Flash vessel; b) Heater; c) Circulating pump

A constriction at the inlet to the flash vessel keeps the acid under a slight pressure so that, although it is heated to 3–4 °C above the outlet temperature of the flash vessel, water cannot evaporate until the acid is free to expand into the evaporator. Delayed boiling in the evaporator itself can be largely prevented by efficient distribution of the acid within the evaporator space. Owing to the relatively high rate of circulation, precipitated solids remain in suspension and are discharged from the system along with the reconcentrated acid.

Multiple-Effect Evaporators. The energy required for water evaporation is normally supplied in the form of low-pressure steam. The steam requirement can be significantly reduced, especially in large-capacity evaporation systems, by coupling several evaporator units together in such a way as to reuse the heat content of the vapors. In the first evaporator unit, heat is supplied in the normal way by indirect steam heating of the acid circuit, but in each subsequent evaporator unit the acid circuit is heated indirectly by vapors produced in the preceding stage. Evaporation systems arranged in this manner are known as *multiple-effect* (or *multistage*) *evaporators* (→ 3. Evaporation, Chap. 2.2.).

The relationship between specific steam consumption and the number of thermally coupled stages in a multiple-effect evaporator is illustrated graphically in Figure 41. A single evaporator unit (i.e., a single-effect system) requires ca. 1.2 t of low-pressure steam per tonne of evaporated water. In a double-effect system this requirement is reduced to only about 0.6 t. Adding a third effect leads to a further reduction, to ca. 0.4 t of low-pressure steam per tonne of water evaporated – in other words, about one-third of the steam consumption of a single-effect system. The alternative of dividing the evaporation system into several concentration steps without such coupling (i.e., use of live-steam heating in each unit) does not reduce the specific steam requirement, though it does reduce the required total heating-surface area relative to a single-effect system.

Figure 41. Theoretical specific steam consumption as a function of the number of effects

Vacuum and Condensation Systems. Multiple-effect evaporator systems are normally operated under vacuum. Depending on the relative cost and availability of electric power, steam, and cooling water, the vacuum may be produced by means of electric vacuum pumps or steam ejectors. When steam ejectors are used, several units are arranged in tandem to generate a relatively low pressure. The effect is enhanced by the installation of preceding and intermediate water-cooled vapor condensers.

Figure 42. Forced-circulation vacuum evaporation system for concentrating sulfuric acid from 20 % to 70 – 80 % H_2SO_4
a) Evaporator heaters; b) Plate heat exchangers; c) Evaporators; d) Acid degasser; e) Ejectors; f) Contact condenser

If spent sulfuric acid containing volatile contaminants is to be concentrated it is best to use surface condensers (tube-bundle heat exchangers with cooling water flowing through the tubes), because with this type of system it is easiest to separate impurities from the vapor condensate. Where the contact (quench) type of condenser with direct water injection is used, the volume of wastewater can be reduced by recirculating part of the condensate.

Construction Materials. Evaporators designed to concentrate sulfuric acid up to 75 % can be fabricated from fiberglass-reinforced polyester or plastic-coated, rubber-lined, enamelled, or lead-coated steel. At higher acid concentrations and temperatures it is possible to use steel lined with FEP sheeting (→ Films, Chap. 6.3.3.) and protected with two layers of carbon bricks. The heat exchangers are usually made of graphite impregnated with phenol resin, in which case they can be operated at wall temperatures $\leq 165\,°C$ and acid concentrations $\leq 84\,\%$ H_2SO_4. Cast ferrosilicon pumps in common use today are capable of withstanding temperatures $\leq 140\,°C$ and a sulfuric acid concentration of ca. 75 %. Special construction material is required for high-stress conditions.

Complete Plant. Figure 42 is a flow diagram of a typical Lurgi-designed plant for vacuum concentration of spent sulfuric acid containing 20 % H_2SO_4 to an H_2SO_4 concentration of 78 % [84]. It comprises a total of four evaporator units. The acid is preconcentrated from 20 % to 54 % H_2SO_4 in the first three units, which are arranged as a triple-effect system. Final concentration to 78 % takes place in a fourth, single-effect stage with live-steam heating. A pressure gradient is maintained across the first three units (a triple-effect stage) to ensure that water continues to evaporate despite a decreasing temperature. Thus, the first stage operates virtually at atmospheric pressure, whereas the third runs at a much lower pressure – 70 mbar, for example, at which point the vapor-condensation temperature is ca. 40 °C. Live steam at 5.5 bar is used for heating the first and fourth stages. This might be derived, for instance, from 3-bar and 28-bar steam, using a steam ejector followed by a steam saturator.

Dilute feed acid is preheated in plate exchangers with the vapor condensate and concentrated production acid. It is then degassed in a bubble-tray column by stripping with vapor from the final concentration stage; this also

serves to recover any sulfuric acid that may still be present in vapors from the final concentration stage. The degassed dilute acid is preheated further in plate exchangers with vapor and steam condensate from the evaporator heaters before being introduced into the acid circuit of the first evaporator.

In the first stage, heated by live steam, water is evaporated from the acid at about 120 °C. The steam supply is adjusted to maintain an acid concentration in the first stage of ca. 25 % H_2SO_4, where the acid boiling point is used as the control parameter. Indeed, the boiling-point elevation above the boiling point of pure water at a predetermined pressure can be used as an exact measure of the H_2SO_4 concentration provided the influence of dissolved contaminants is taken into account. In the second stage, where the acid is heated indirectly by vapors from the first stage, more water is evaporated at about 95 °C despite the higher acid concentration; this is possible because of the lower pressure. Vapors from the second stage provide heat for acid circulating in the third stage, where it is concentrated to about 55 % at ca. 65 °C under an appropriate vacuum. As mentioned previously, live steam is again used for final concentration to 78 % in the fourth stage.

Because of the pressure gradient, the acid need not be pumped from one stage to the next. After the fourth stage, the concentrated acid is cooled indirectly with incoming dilute acid in a plate heat exchanger and than pumped to storage tanks. Vapors from the third-stage evaporator are mixed with scrubbed vapors from the final evaporator as they leave the degasifier column, and then passed through a surface condenser. Uncondensable gases emerging from this condenser are exhausted through a multistage vacuum system consisting of steam ejectors and auxiliary surface condensers, and are finally discharged to the atmosphere.

The steam condensate from the heating elements of the first and fourth evaporator stages is collected, expanded, and cooled through indirect heat exchange with the dilute acid before being discharged. Vapor condensate from the second and third stages is similarly utilized for preheating the spent acid in plate exchangers, after which it is mixed in a collector with condensate from the condensers of the vacuum system. The residual heat of the accumulated vapor condensate is utilized for initial preheating of the spent acid.

The process thus takes maximum advantage of the heat content of the vapors by means of a multiple-effect arrangement of the evaporators, and it also recovers the maximum possible amount of waste heat from the condensate for preheating purposes. This is of vital importance in view of the continuously rising cost of energy.

The maximum water-evaporating capacity of a single-train multistage unit with forced-circulation evaporators is presently in the range of 8 – 10 t of water per hour.

Venturi Reconcentration Process. The venturi sulfuric acid reconcentration system developed by Lurgi is preferably integrated thermally into a sulfuric acid production plant in such a way as to make use of waste heat and thereby avoid the cost of heating with steam or fossil fuels. The system is designed to utilize sensible heat from the tail gases as well as the relatively low-level heat content of acid circulating in the sulfur trioxide absorption system of an acid production plant [122, 130].

The most significant feature of the venturi reconcentration process is that – at atmospheric pressure – water is evaporated from dilute sulfuric acid at a temperature far below the boiling point of the acid solution. Gases passing through the venturi system become laden with water vapor in proportion to the water-vapor partial pressure of the acid (which is a function of the H_2SO_4 concentration and the temperature), carrying this water out of the reconcentrator system for subsequent discharge to the atmosphere. Venturi systems have long been used in gas-cleaning plants as gas scrubbers, but it was only in the early 1970s that Lurgi developed venturi systems specifically designed for acid concentration. These have meanwhile rendered satisfactory service in various industrial plants.

The concentration unit consists of a venturi scrubber into which the acid is injected cocurrent with the gas flow, followed by a tower in which dilute spent acid and gas interact in countercurrent. Despite a short gas retention time, water becomes equilibrated between the acid and the vapor because the two mix so efficiently and intimately in the venturi unit. The carrier gases acquire a higher moisture load in such a two-stage evaporation system with two separate acid

Figure 43. Two-stage venturi reconcentration system utilizing acid waste heat from a double-absorption sulfuric acid plant
a) Acid heat exchangers; b) Dilute acid tank

circuits running at different H_2SO_4 concentrations than they would in any single-stage system, so the water-evaporation capacity is greater for the same gas throughput. At the same time, the H_2SO_4 content of discharge gases remains extremely low, even when the sulfuric acid concentration is raised to more than 70 %, on account of the lower concentration of acid circulating in the second evaporation stage. It has been demonstrated in practice that venturi reconcentrators also function well as tail-gas scrubbers, substantially reducing the natural H_2SO_4 content of tail gases from a sulfuric acid plant [75]. The heat required for dehydration and water evaporation during concentration of the acid is supplied directly to the system as the sensible heat content of the carrier gases as well as by indirect heating of the concentrator acid circuits with product acid from the main acid plant. The concentrating capacity can be increased by introducing air heated with excess heat from the contact plant along with the hot, dry tail gas from the sulfuric acid plant.

The temperature demand associated with heat suitable for a venturi reconcentrator system, which has a comparatively low operating temperature, is quite compatible with the substantial amount of waste heat available in acid circulating in the sulfur trioxide absorption system of a sulfuric acid plant, which must in any case be dissipated. The venturi reconcentrator system is thus a very good way of making economical use of low-level waste heat from a sulfuric acid plant. If the concentrator unit is thoroughly integrated into the waste-heat system of the acid plant, ca. 22 – 26 t/h of water can be evaporated with the waste heat from a 1000-t/d sulfuric acid plant.

Figure 43 is a diagram of a two-stage venturi reconcentrator designed for evaporating waste sulfuric acid originally containing 30 % H_2SO_4 until it reaches a concentration of 70 %. Tail gases leaving the final sulfur trioxide absorber of the sulfuric acid plant at ca. 80 °C are passed directly into the venturi reconcentrator. Circulated acid, at a concentration of about 70 % and also heated to ca. 80 °C, is injected at the top of the venturi unit in cocurrent with the gases. Adiabatic evaporation of water cools the gases and acid to about 74 °C. A special nozzle grate installed in the outlet of the venturi section provides additional turbulence and assists in subsequent separation of gas from the liquid phase.

Gases leaving the venturi section typically have a water content of ca. 20 g/m^3. They are introduced into the bottom of a subsequent tower through which they rise in countercurrent with a spray of 55 % sulfuric acid from the second acid circuit, again heated to about 80 °C. Within the tower the water content of the gases increases to about 80 g/m^3. A droplet separator at the tower outlet removes any remaining droplets from the gases, which are subsequently discharged to the atmosphere via a stack. Acid accumulating in the tower sump becomes cooled to ca. 70 °C as a result of the water evaporation. Acid in both concentrator circuits is heated in Teflon tube-

bundle heat exchangers by 98.5 % sulfuric acid at ca. 100 °C derived from the intermediate and final absorbers of a double-absorption sulfuric acid plant.

The dilute acid subject to concentration, which is about 30 % in H_2SO_4, is fed to the tower sump of the second stage. Preconcentrated acid from the second stage simply overflows from the sump of the tower into the sump of the first-stage venturi unit. The 70 % reconcentrated acid likewise overflows from the sump of the venturi unit to product storage.

Operation of a venturi reconcentrator system is quite straightforward. The feed rate of the spent acid is controlled relative to the acid concentration in the venturi circuit so as to maintain the desired product-acid concentration; no further control measures are required.

Venturi reconcentrators are designed for a gas-pressure drop of 15 – 20 mbar. Apart from power consumed by the supplementary blower capacity and the electric drives of the acid circulation pumps, no additional energy is required.

Since they are relatively compact, venturi reconcentrators are well-suited to retrofit installation in existing sulfuric acid plants.

The first of the venturi acid-reconcentration systems has been in operation at Süd-Chemie AG at Kelheim, in the Federal Republic of Germany, since 1972. It concentrates dilute spent sulfuric acid to a level of about 70 %, and is associated with a double-absorption sulfuric acid plant designed for a capacity of 220 t/d. The largest venturi reconcentrator unit, designed for a gas throughput of 200 000 m^3/h, is thermally integrated into a 2000-t/d double-absorption sulfuric acid plant at the Inspiration Copper works in Arizona (United States). Venturi reconcentrators thermally integrated into sulfuric acid plants are also used for processing spent acids saturated with ferrous sulfate, encountered, for example, as scrubbing acids in the gas-cleaning systems of pyrite roasting plants.

Submerged-Combustion Process. Submerged-combustion processes are sometimes used for concentrating spent acids with high salt contents to 60 – 70 % H_2SO_4 [128, 131–134]. Liquid or gaseous fuels and a burner are used to generate hot flue gases at 1500 – 1600 °C that are forced through concentrated acid via an immersion tube. The flue gases are cooled by the adiabatic evaporation of water, simultaneously absorbing water vapor at a rate that depends on the water-vapor partial pressure above the acid. Depending on the acid concentration, the bath temperature remains in the range of ca. 120 – 150 °C. The flue gases, which leave at about the same temperature, contain up to ca. 60 vol % water vapor. Before being discharged to the atmosphere, these gases are cleaned and cooled in a liquid separator, a scrubbing and cooling tower, a wet precipitator and, if necessary, a special sulfur dioxide scrubbing tower.

Figure 44. Submerged-combustion evaporator for gas or oil firing
a) Oil inlet; b) Igniter; c) Air inlet; d) Acid inlet; e) Acid outlet; f) Acid circulating tube; g) Immersion tube; h) Vapor outlet; i) Combustion chamber; j) Gas inlet

Figure 44 is a schematic diagram of a submerged-combustion evaporator. The evaporator vessel is constructed from lead-coated steel, and in most cases it is brick-lined as well. The combustion chamber is located above the vessel, from which the burner projects downwards beneath the surface of the acid. A circulating tube is positioned concentrically around the immersion tube, through which liquid is forced by the ascending flue gases. Apart from causing vigorous circulation of the acid, this also promotes favorable mass and heat transfer between gas and liquid.

Spent acid is fed continuously either through a separate nozzle, as shown in Figure 44, or through a dephlegmator placed on top of the gas outlet [131, 132]. A mixture of concentrated acid and precipitated salts leaves the evaporator through an overflow pipe.

This system of direct heat transfer from the flue gases to the acid largely avoids the incrustations that would normally be deposited on heating surfaces, especially during the evaporation of salt-laden spent acid. Nevertheless, the high flue-gas temperature and the consequent high wall temperature of the immersion tube impose very heavy demands on the construction materials.

The jacketed combustion chamber is cooled by incoming combustion air passing through the jacket. The immersion tube, made of cast iron, is protected in its uncooled upper region by an internal insulating lining. The lower part of the immersion tube is cooled by the acid. The critical zone with respect to corrosion and erosion is the outside of the immersion tube above the top of the circulating tube. With time, this part of the immersion tube gradually becomes eaten away to the point where the lower, submerged part actually falls off, limiting the service life of the tube to a maximum of ca. 2000 operating hours [133].

A submerged-combustion evaporator is useful, for example, for concentrating the contaminated salt-bearing sulfuric acid arising from TiO_2 pigment manufacture from 21 % to a final concentration of 65 – 68 % H_2SO_4 [133]. About 27 m^3/h of spent acid with a specific gravity of 1.3 kg/L is fed to an evaporator vessel with a capacity of ca. 3 m^3. At the designed water-evaporation rate of ca. 1.95 t/h, 3.1 – 3.2 GJ of energy in the form of fossil fuel is consumed per ton of evaporated water. However, the specific heat requirement of the submerged-combustion evaporation process can be reduced (in this case, for example, to about 1.9 GJ per tonne of water evaporated) [133] by utilizing the heat of condensation of the vapors for concentrating spent acid in a preceding stage.

4.3.3. Concentration to 93 – 98 % H_2SO_4

Vapors evolved during the concentration of spent sulfuric acid to a more highly concentrated state (93 – 98 % H_2SO_4) contain significant quantities of gaseous sulfuric acid. It is therefore absolutely obligatory that the vapors be cleaned before discharge to the atmosphere. Concentration may involve either direct or indirect heating, with the latter approach applicable both at normal pressure and under vacuum.

Chemico Direct-Fired Drum Concentrator. The Chemico drum-concentrator process [135] was developed in the 1920s. It is used especially for concentrating spent acids from the explosives industry. The principle is similar to that of the submerged-combustion method. Flue gases resulting from the combustion of gas or fuel oil are passed through an immersion tube into the acid to be concentrated, which flows countercurrent with the gases through several vessels arranged in cascade fashion (Fig. 45). The vessels are made of lead-lined steel protected with up to three layers of acid-proof bricks [136, 137]. The immersion tubes are fabricated from ferrosilicon.

Figure 45. Chemico drum concentrator
a) Combustion chamber; b) Concentrator; c) Gas cooler/acid preheater

Flue gases enter the concentrator at ca. 600 °C [128]. Because of the relatively low flue-gas temperature, there is practically no thermal decomposition of the sulfuric acid, so almost no sulfur dioxide is formed [131].

The concentrator is subdivided into two chambers containing acid at different concentrations. In the first chamber, into which the hot flue gas enters and from which concentrated acid is discharged, the acid concentration is maintained at 93 – 94 %. The gas then passes to the second chamber at 250 – 260 °C. A portion of the hot flue-gas stream may be introduced directly into the second chamber for the purpose of controlling the acid concentration. Flue gases leaving the second chamber at 180 – 200 °C are cooled to 130 – 150 °C in a second vessel. The feed acid (usually at a concentration of 70 %) is introduced into this vessel. Discharged gases must be demisted and cleaned.

The Chemico process shares with the submerged-combustion method the advantage that it avoids heating surfaces prone to acquiring deposits during the concentration of salt-contaminated spent sulfuric acid; all the requisite heat is supplied by the flue gases. Moreover, water evaporation takes place not in the boiling range of sulfuric acid but about 50 °C below the atmospheric pressure boiling point [136]. The process is suited to the concentration of relatively large volumes of acid. Single-train plants have been designed with capacities of up to 18 t/h of 93 – 94 % acid.

A significant drawback of the Chemico process is the large amount of contaminated waste gas that is produced, the cleaning of which is very costly. A scrubbing tower and an electrical gas-cleaning system were formerly used for this purpose, but modern plants employ venturi scrubbers almost exclusively. These are combined with cyclones for separating droplets. The sulfuric acid content of the waste gas from such a plant is reported to be 75 – 200 mg/m^3 [135].

Spent acid may also contain organic impurities, in which case these and their decomposition products would be entrained by the waste gases and subject to only partial elimination in the waste-gas cleaning system. When processing spent acid containing nitrates or nitrogen oxides, NO/NO_2 liberated during concentration would similarly not be removed by the gas-cleaning system, resulting in a visible plume at the stack. In view of the increasing stringency of environmental regulations in many locations, the utilization of this process is becoming more and more problematic [137].

Concentration Processes Involving Indirect Heating.

Pauling – Plinke Process. In this process, spent sulfuric acid is concentrated to 95 – 98 % H_2SO_4 under normal pressure by indirect heating with flue gases. The process was developed by Pauling beginning in 1915, and the necessary equipment is built by Plinke [138].

Actual concentration takes place in a cast iron vessel (a "Pauling pot") suspended in a furnace. The furnace is surmounted by a distillation column (in most cases a bubble-tray column) made of silicon iron (see Fig. 46). Vessels of this type are built with a useful volume of up to 12 m^3; above about 3 m^3 an anchor mixer (also made of silicon iron) is included [138].

Figure 46. Pauling – Plinke pot concentrator
a) Condenser; b) Stripping column

Spent acid (ca. 70 % H_2SO_4) is fed to the column from above, and it flows downward into the vessel in countercurrent with the exhaust vapors. Incoming acid is concentrated to 82 – 85 % H_2SO_4 by heat and mass transfer with the vapors; simultaneously, sulfuric acid present in the vapors is condensed almost completely. If the spent acid has an H_2SO_4 content greater than 70 % the acid is admitted at a tray lower in the column.

The sulfuric acid concentration in the vessel itself must be kept above 80 % to avoid corrosion [136]. In most cases, the concentration of the boiling acid is maintained above 95 % (corresponding to a boiling temperature of ca. 330 °C). Under these conditions, the average corrosion

loss-rate is about 8 – 10 mm per year [138]. A service life of ca. 3 – 5 years is achieved by designing the vessel with a sufficiently thick wall.

The acid is heated indirectly by flue gases passing around the vessel. These flue gases, generated by burning fuel oil or gas, enter the furnace cavity at 800 – 1100 °C and leave it at ca. 450 °C. The mean heating-surface load of the vessel is ca. 144 000 $kJm^{-2} h^{-1} = 40 kW/m^2$ [138]. The high flue-gas temperature means that the wall material of the vessel on the furnace side is subject to heavy stress.

Flue gases leaving the furnace can be utilized for preheating the combustion air to ca. 200 °C. Part of the flue-gas stream is cooled to 200 – 250 °C and recycled to the furnace cavity. Such combustion-air preheating and flue-gas recirculation raises the furnace efficiency (ratio of heat supplied to the vessel to applied fuel energy) to 80 – 83 %.

Hot, concentrated sulfuric acid is extracted continuously from the vessel. It is cooled indirectly against water in special coolers (pot coolers) [138], where most of the dissolved inorganic impurities are precipitated. Organic impurities in the feed acid are decomposed by oxidation within the evaporator: either by the high temperature alone or – if necessary – by the addition of nitric acid.

Vapors leaving the top of the discharge column at ca. 130 °C still contain as much as ca. 1 % sulfuric acid vapor, together in some cases with sulfur dioxide, nitric oxide, and organic substances, as well as inert gases [128, 138]. The water vapor is separated in a condenser, whereas noncondensable components are passed on to a waste-gas cleaning system.

All concentration processes involving indirect heating, including the Pauling – Plinke process, have the advantage over directly heated processes that the volume of resulting waste gases to be cleaned is low. However, they suffer the drawback of heating surfaces that are prone to scaling with precipitated impurities from the spent acid. This necessitates frequent checking and entails high maintenance costs [136].

In the Pauling – Plinke process, the ratio of heating surface to vessel volume, and thus the ratio of the attainable heat-transfer rate to the rate of acid production, is relatively low. Because of the limited evaporation capacity of a single unit, high throughput requires several parallel units [136]. Typically, 0.6 – 1.2 t/h of water can be evaporated per vessel [137].

Falling-Film Evaporation Process. In this process, spent sulfuric acid descends as a thin film on the inner surface of an externally heated tube. This arrangement provides a favorable heat-transfer rate and a large surface from which water can evaporate. Evaporated vapors ascend in countercurrent with the acid, and are substantially freed from entrained sulfuric acid vapor and mist by the scrubbing action of entering spent acid in a column surmounting the evaporator, similar to that in the Pauling – Plinke process.

A falling-film evaporator process was formerly operated by Du Pont under vacuum conditions (27 – 40 mbar), with indirect heating by steam at 25 – 30 bar [139].

A more recent process – the BOSAC process, developed by Bofors – operates under normal pressure with indirect heating by flue gases [137, 140–142]. When the emerging flue gases are used for preheating the combustion air, a thermal efficiency of 82 – 85 % is achieved [141].

Bayer – Bertrams Process. This process is applicable from atmospheric pressure up to about 5 bar; indirect heating is supplied by a heat-transfer medium [137, 143, 144]. The heat carrier is a salt melt (nitrate/nitrite) that is heated indirectly by flue gases in a separate furnace.

The modern version of the process uses tubes of borosilicate or pure quartz glass with a diameter of 150 – 400 mm. Spent acid is fed to the stripping column at a concentration of 65 – 85 % H_2SO_4 and is concentrated to ca. 96 – 98 % at 300 – 330 °C. Organic impurities that may be present are decomposed almost completely, with assistance as necessary from an added oxidant.

A special advantage of the falling-film concentration process is the favorable ratio of heating surface to acid volume. By connecting a large number of tubes in parallel, an evaporation capacity comparable to that of a Pauling – Plinke unit can be achieved. A falling-film evaporator plant composed of 12 tubes is reported to have a capacity of 1 t/h of 96 – 97 % sulfuric acid starting from 65 – 70 % acid, which corresponds to a water-evaporation rate per tube of ca. 50 kg/h.

Vacuum Processes. Processes in this category transform spent sulfuric acid directly into highly concentrated material. The principle is

comparable to that used in a vacuum process for evaporation to intermediate concentration. Problems are encountered with the materials of construction, however, and it is essential that special cleaning systems be provided to remove evaporated sulfuric acid from the emitted vapors. It is not possible to make use of the multiple-effect principle because of the high temperatures required. The acid is heated indirectly with high-pressure steam at every stage.

Simonson – Mantius Process. Developed in 1921, this is one of the most well-known vacuum methods for attaining high acid concentrations. Most of the corresponding plants are multistage units operating with either natural or forced circulation, depending on their design, and with separate heat exchangers or heating tubes installed directly in the evaporator vessels [145]. The evaporator vessels themselves are made of lead-lined steel further protected by acid-proof bricks or a layer of graphite or enamel. The heat exchangers or heating tubes are made of lead, graphite, silicon iron, or tantalum.

The Simonson – Mantius process has been developed further by Chemetics International Ltd. [137, 146]. In the Chemetics version of the process, the evaporators are made of enamelled steel or, in the case of very small units, glass-lined steel, and they incorporate bayonet heaters made of tantalum. In its standard form the process leads to 93 % sulfuric acid, but it can be designed to provide concentrations of 95 – 96 % if desired [137].

The largest existing unit concentrates approximately 28 t/d of sulfuric acid (calculated as 100 % H_2SO_4) from 70 % H_2SO_4 to 93 %; this corresponds to a water evaporation capacity of ca. 10 t/h [137]. Only acids that do not contain solids, or which will not produce accretions during concentration, can be treated by this process.

Corning/EIVS Process. The Corning/EIVS process is based on horizontal evaporators [147]. Spent acid flows continuously through a horizontal cylindrical vessel made of borosilicate glass. PTFE deflectors are used to prevent backmixing. The acid is heated indirectly with 15-bar steam, which is passed through an internal tantalum tube bundle. The operating temperature of the evaporators is limited to a maximum of 180 °C to restrict corrosion.

Spent acid can be concentrated from 65 % H_2SO_4 to 88 % in a single stage operating at an absolute pressure of 93 mbar. For triple-stage concentration to 95 % H_2SO_4, pressures in the individual stages are 133, 40, and 13 mbar [147]. The steam consumption is reported to be ca. 2 t of steam per tonne of evaporated water, corresponding to ca. 4 GJ per tonne of H_2O.

4.4. Production of Oleum

Oleum ("fuming sulfuric acid") [*8014-95-7*] consists of a solution of sulfur trioxide in 100 % sulfuric acid. Normally, the oleum concentration is expressed in terms of the mass content of so-called "free" sulfur trioxide. Part of the dissolved sulfur trioxide reacts with sulfuric acid to form higher sulfuric acids such as disulfuric acid, $H_2S_2O_7$ (see Section 2.2). Pure sulfur trioxide (Chap. 8) corresponds theoretically to oleum with 100 wt % "free" sulfur trioxide.

Oleum is produced industrially in contact plants, where sulfur trioxide-containing gases are passed through a special oleum tower. In a double-absorption plant this is located upstream from the intermediate absorber; otherwise it is upstream from the final absorber.

Oleum should contain at least 20 – 22 % "free" sulfur trioxide to avoid problems with construction materials. The upper concentration limit of about 36 % is determined by the partial pressure of sulfur trioxide in the gases as well as the oleum temperature in the oleum tower, which in turn establishes the sulfur trioxide vapor pressure of the oleum (see Section 2.1 and Fig. 6). The dependence of oleum vapor pressure on temperature and concentration in the range of interest to industry is shown in Figure 47 [148–150]. Oleum formation by sulfur trioxide absorption can proceed only so long as the oleum vapor pressure remains below the partial pressure of sulfur trioxide in the gas phase. It follows from the vapor-pressure curves that, if the oleum temperature is 60 °C and the partial pressure of sulfur trioxide in the contact gases is 115 mbar, for example, the theoretical maximum attainable oleum concentration is about 37 %. This corresponds to the sulfur trioxide partial pressure in gas at a total pressure of 1.12 bar produced in the first three beds of a (3 + 1) double-absorption sulfuric acid plant operating on a feed gas initially containing 10 vol % SO_2, assuming the sulfur dioxide conversion at this point is 95 %.

Figure 47. Vapor pressure of oleum as a function of free SO_3 content and temperature
a) 80°C; b) 70°C; c) 60°C; d) 50°C; e) 40°C

The potential rate of oleum production is limited by the water balance in the contact plant. This is determined by the rate at which water vapor enters the plant – with the combustion air in a sulfur-burning plant, or in roaster or decomposition gases in a "cold-gas" plant – and is subsequently absorbed into the acid circuit in the dryer, since sufficient sulfur trioxide must remain in the process gas after the oleum tower to maintain an acid concentration of 98.5 % in the absorbers. Therefore, the lower the rate at which water enters the acid system via the dryer, the higher the proportion of sulfur trioxide available for oleum production.

Oleum towers are similar in design to modern acid-plant main absorbers. However, because of the specific corrosion behavior of oleum, these towers can be fabricated from stainless steel without a brick lining. Sulfur trioxide-ontaining gas enters the oleum-irrigated packed tower at ca. 200 °C. Depending on the desired product concentration, the tower is irrigated with 22 % or 35 % oleum at a temperature of ca. 40 – 50 °C. Oleum of higher concentration leaves the tower at ca. 60 – 80 °C. It is adjusted to the desired final oleum concentration by addition of concentrated sulfuric acid from the intermediate or final absorber of the contact plant, and is then cooled in special coolers. Product is withdrawn from the oleum circuit downstream from the cooler. Oleum of higher concentrations (e.g., 60 – 65 %) is obtained by mixing 20 – 36 % oleum with pure sulfur trioxide.

5. Construction Materials

(→ Construction Materials in Chemical Industry)

The traditional construction material for use in a sulfuric acid plant based on the lead chamber or tower process was, of course, lead. By contrast, modern contact-process plants are constructed mainly from iron and steel. This is a striking example of the extent to which the selection of construction materials depends on the nature of a specific process and its associated operating conditions [151–153]. Conversely, new processes frequently become practical only with the development of appropriate materials. This is particularly true of acid-heat recovery systems, which are of major importance in the further development of sulfuric acid technology.

Elevated sulfuric acid temperatures are essential for the economical recovery of acid waste heat. This mandates the use in acid coolers and heat exchangers of corrosion-protected materials that are able to withstand attack not only by the acid itself (with the aid of anodic protection as appropriate) but also, given the elevated wall temperature, attack by the cooling fluid.

One general problem relates to the extent to which a particular material will display in service the same behavior that has been observed in a laboratory with respect to corrosion rates under specific conditions (as a function of oxygen concentration and temperature, for example). Many additional parameters that influence corrosion behavior are relevant in industrial practice. For example, dissolved impurities – even in minute concentrations, which may be difficult to determine analytically – as well as suspended solids and sulfuric acid flow velocities are all significant, as is the treatment and processing of a construction material prior to its installation.

Data acquired through systematic laboratory tests based on pure media, and even empirical data derived from practical experience, are therefore of only limited validity for predicting the behavior of a given material in a particular application. General statements regarding the suitability of a construction material with respect to sulfuric acid over a defined range of concentration and temperature should never be taken too literally.

A comprehensive list of important empirical values is provided in the Dechema materials tables [154].

For concentrations $\leq 90\,\%$, sulfuric acid is classified as a nonoxidizing acid, but concentrated sulfuric acid and oleum both exhibit oxidizing properties. This is the reason, for example, why hot, concentrated sulfuric acid reacts with copper and silver to form sulfur dioxide rather than hydrogen:

$$2\,H_2SO_4 + M^0 \longrightarrow M^{II}SO_4 + SO_2 + 2\,H_2O \qquad (21)$$

Carbon is also oxidized by hot, concentrated sulfuric acid and oleum, again generating sulfur dioxide. Corrosion rates for metallic materials in sulfuric acid are determined largely by the solubilities of the respective metal sulfates as a function of acid concentration and temperature.

5.1. Metallic Materials

Lead. The high corrosion resistance of lead over a wide range of sulfuric acid concentrations and temperatures is due exclusively to the formation of a passive layer of lead sulfate ($PbSO_4$) on the metal surface. The solubility of lead sulfate in sulfuric acid increases with increasing acid concentration, and the corrosion rate increases accordingly. Lead can be used with H_2SO_4 concentrations up to 78 % and temperatures $\leq 110\,°C$. Chloride ions strongly enhance the corrosion, because they penetrate the passive layer. Copper-containing lead is the most corrosion-resistant form apart from high-purity lead itself. Lead plays essentially no role whatsoever in a dry-gas contact sulfuric acid plant. Only in wet-catalysis plants ($\leq 78\,\%$ H_2SO_4) and especially in wet gas-cleaning systems is lead still relatively widely used in such equipment as scrubbers, wet-gas precipitators, tube-bundle coolers, piping, valves, and pumps. Even here it is increasingly being replaced by plastics.

The main drawbacks of lead are high density, low mechanical strength, and high installation cost.

Mild Steel. Sulfuric acid with a concentration $> 60\,\%$ produces an iron sulfate layer on mild steel surfaces. The solubility of iron sulfate decreases markedly at elevated acid concentrations, and the corrosion rate displays a similar steep decline as the H_2SO_4 concentration is increased above 78 %. At H_2SO_4 concentrations $> 100\,\%$ (i.e., in the presence of free sulfur trioxide) corrosion increases rapidly up to a sulfur trioxide content of 30 %, declining steeply at even higher sulfur trioxide concentrations. The passive layer is quickly eroded at elevated acid-flow velocities, and the corrosion rate rises accordingly. Chloride ions contribute substantially to corrosion, because they penetrate the passive layer (pitting corrosion).

Steel is used in conjunction with 68 – 100 % sulfuric acid at low temperatures for both storage and handling vessels, and it is the preferred construction material for all reaction vessels in contact plants producing 93 – 98.5 % sulfuric acid. The corrosion resistance of steel declines as the temperature rises from 50 °C to 80 °C, which is why steel surfaces in reaction vessels with turbulent flow areas are protected by a lining of acid-proof bricks. Dryers and absorbers frequently have a layer of plastic sheeting between the steel shell and the brick lining. Steel is unsuitable for acid temperatures above 80 °C. When acid piping is made of steel itis advisable to limit the flow velocity to about 0.5 m/s. Steel is also used for oleum, but predominantly in situations where the "free" sulfur trioxide content exceeds 22 – 23 %. If the "free" sulfur trioxide content is low, enamelled steel is suitable, even at elevated temperature.

Austenitic Stainless Steel [183]. Under oxidizing conditions, sulfuric acid forms a passive layer on austenitic stainless steel. This layer consists of iron oxide and chromium oxide together with incorporated sulfates, which improves its stability. At higher flow velocities, however, and under reducing conditions, the protective layer is eroded, causing the corrosion rate to increase. Reducing conditions result, for example, if sul-

furic acid is left standing in a shut-down plant for extended periods without being moved or aerated. Chloride ions also contribute to depassivation. In a modern sulfuric acid plant, austenitic stainless steel (e.g., material no. 1.4571) is used in conjunction with concentrated acids up to 85 °C, and it can withstand acid velocities up to ca. 1.0 m/s (in pipelines, for example). At higher temperatures, the corrosion resistance decreases sharply. However, the temperature resistance can be increased to about 160 °C by applying anodic protection (passivation of a metallic construction material by anodic polarization with direct current) [68]. Anodic protection not only reduces the corrosion rate for certain grades of stainless steel by two orders of magnitude, but it also prevents stress-corrosion cracking. It is increasingly being used to safeguard stainless-steel acid coolers, especially in acid waste-heat recovery systems.

Because of the limitations of standard stainless steels (types 304, 316, etc.) at higher temperatures and high H_2SO_4 concentrations, considerable effort has been directed toward the development of special forms of stainless steel. Several stainless steels with austenitic and ferritic structures are now available for sulfuric acid service at temperatures up to 140 °C (in certain cases up to 200 – 220 °C) and flow velocities up to 2.5 – 3 m/s. Anodic protection is not required for such stainless steels. The most familiar alloys for this purpose include:

Sandvik SX
Saramet
Hastelloy C 276 (DIN 2.4819)
Cronifer 2803 (DIN 1.4575)
Alloy 20 (Carpenter 20)
DIN 1.4529, 1.4539
DIN 1.4562, 1.4563

The above-mentioned materials are used mainly for the fabrication of heat exchangers, piping, irrigation systems, and to a certain extent drying/absorption towers. A similar development has occurred with cast materials. Pumps, valves, etc. are now available for sulfuric acid absorption systems operating at temperatures up to 200 °C. The best-known alloys of this type are the Lewmet family and Rheinhütte's alloys 1.4136 S/HRS. Cast iron was for decades the dominant construction material for sulfuric acid services but itis now being replaced in almost all fields of applications by these modern alloys.

Acid-Proof Cast Iron. Certain grades of cast iron alloyed with chromium or copper are very stable at H_2SO_4 concentrations of 90 – 99 % and temperatures $\leq$ 100 – 120 °C. Cast iron is used mainly for acid piping, irrigation systems in acid towers, and irrigation coolers. It is not suitable for use with oleum; although the surface-wear corrosion rate is extremely low, salts tend to form alongside the graphite lamellae, giving rise to cracks and material failure.

Silicon Iron. Silicon iron contains 14 – 18 % silicon. Its high resistance to acids is due to the formation of a protective layer of silica on the surface of the casting. It is therefore somewhat sensitive to hydrogen fluoride. Silicon iron is highly resistant to sulfuric acid at all concentrations, from extremely dilute up to highly concentrated, and over a wide temperature range. Silicon iron with at least 16 % Si is useful for pumps and agitators under the high thermal stress encountered in a sulfuric acid concentration plant. Unfortunately, however, it is highly sensitive to both thermal and mechanical shock. It also cannot be used for oleum, because its silicide content is subject to oxidation, and the corresponding salt formation gives rise to cracks and ruptures along the grain boundaries.

5.2. Nonmetallic Materials

Plastics. Plastic materials [for example, polypropylene, poly(vinyl chloride), or polyethylene] are preferred for use in systems with low acid concentrations because of their high resistance to corrosion. Their usefulness is limited, however, by high coefficients of thermal expansion and a loss of mechanical strength with increasing temperature, resulting in creep. Poly(vinyl chloride) (PVC) can be used with acid concentrations $\leq$ 78 % H_2SO_4 at temperatures $<$ 50 °C, polypropylene (PP) at concentrations $\leq$ 90 % and temperatures $<$ 80 °C. On account of its excellent corrosion resistance, however, polytetrafluoroethylene (PTFE) is applicable even at high acid concentrations ($\leq$ 100 %) and temperatures $>$ 100 °C for equipment and

pipe linings as well as in special acid heat exchangers.

Graphite. Nonporous carbon and graphite are regarded as resistant construction materials under nonoxidizing conditions (i.e., in sulfuric acid with a concentration up to 90 %), and they are used in condensation towers, coolers, storage tanks, and pumps at temperatures $\leq 170\,^{\circ}C$.

Glass. Because of its excellent corrosion resistance at all acid concentrations, glass is used in special acid heat exchangers – for heating dilute waste acid with hot absorber acid, for example. A significant disadvantage of this material is its fragility.

Enamel. Acid-proof enamel offers the same resistance as glass. Newly developed enamel grades are largely insensitive to thermal shock. Enamelled steel and cast iron are used for acid piping at elevated temperature.

6. Uses of Sulfuric Acid and Economic Aspects

Sulfuric acid is one of the most widely used of all industrial chemicals. But, as has already been noted, most of its uses can be considered as indirect, because it functions as a reagent rather than as an ingredient: surprisingly little of it appears in end products, and most ends up as spent acid or some type of sulfate waste. A number of products do incorporate the sulfur of sulfuric acid, but nearly all of them are low-volume, specialty items.

6.1. Indirect Uses

The largest single consumer of sulfuric acid by far is the *fertilizer* industry. Most goes into the production of phosphoric acid, which in turn is used to manufacture such fertilizer materials as triple superphosphate and mono- and diammonium phosphates. Lesser amounts are used for producing superphosphate and ammonium sulfate. About 60 % of the sulfuric acid produced is utilized in fertilizer manufacture [35, 155]. In the Federal Republic of Germany, however, the fertilizer industry accounts for a much less significant proportion of total sulfuric acid consumption: only about 14 % [33]. This is because of the historical predominance in that country of thermally treated phosphates and basic slag (a byproduct of steel making) relative to chemically produced phosphate fertilizers. Although thermal phosphates are generally in decline in relation to total consumption owing to their high cost, the balance is accounted for by increased use of fertilizers based on imported phosphate intermediates rather than an expansion in the domestic basic phosphate processing industry.

Elsewhere in industry, substantial quantities of sulfuric acid are used as an acidic dehydrating reaction medium in *organic chemical* and *petrochemical* processes involving such reactions as nitration, condensation, and dehydration, as well as in *oil refining*, in which it is used for refining, alkylation, and purification of crude-oil distillates.

In the *inorganic chemical* industry sulfuric acid is used notably in the production of TiO_2 pigments, hydrochloric acid, and hydrofluoric acid.

In the *metal processing* industry, sulfuric acid is used for pickling and descaling steel, for leaching copper, uranium, and vanadium ores in hydrometallurgical ore processing, and in the preparation of electrolytic baths for nonferrous-metal purification and plating.

Certain *wood pulping* processes in the paper industry require sulfuric acid, as do some *textile* and *chemical fiber* processes and *leather tanning*.

6.2. Direct Uses

Under certain conditions, sulfuric acid is occasionally used directly in *agriculture* for rehabilitating extremely alkaline soils, such as are found in the desert regions of the western United States. This is not a very important use in volume terms, however.

Probably the largest use of sulfuric acid in which the sulfur becomes incorporated in the final product is *organic sulfonation*, particularly for the production of detergents [156]. Other minor organic chemicals and pharmaceuticals are also made by sulfonation.

One of the most familiar consumer products containing sulfuric acid – the *lead-acid battery* – accounts for only at tiny fraction of total sulfuric acid consumption.

6.3. Economic Aspects

Table 1 provides a summary of world production and consumption of sulfuric acid for the years 1982 and 1992, during which world production increased by 9.9 % (despite a drop of 10.4 % between 1989 and 1992).

Table 1. Sulfuric acid production and consumption for 1982 and 1992 (10^3 t of 100 % H_2SO_4) [source: British Sulphur]

7. Analytical Techniques

Concentration and impurities content are the most frequently measured parameters for sulfuric acid quality-control purposes. In addition, quantitative determinations of sulfur dioxide and trioxide are essential in the production plant for monitoring the performance of the process and ensuring that the tail-gas composition conforms with environmental regulations. More detailed accounts of analytical methods are available in [157–159].

7.1. Concentration Measurement

The simplest manual method for determining sulfuric acid concentration is density measurement with a densitometer. This method is reliable for sulfuric acid with a strength of up to 95 % provided the influence of temperature is taken into account. The method can also be extended to acids of higher concentration and also to oleum by first diluting a measured sample under controlled conditions and then measuring its density.

Continuous monitoring of acid concentration in an industrial sulfuric acid plant is generally accomplished by means of automatic recording devices based either on conductivity or ultrasonic measurement. The common chemical laboratory approach to measuring sulfuric acid content is volumetric titration with sodium hydroxide solution, but in certain cases it is necessary to resort to gravimetric determination of precipitated barium sulfate.

7.2. Measurement of Impurities

Iron, arsenic, sulfur dioxide, nitrogen compounds, chloride, and fluoride in sulfuric acid can be determined by conventional means as follows:

Iron. Iron content can be established either photometrically after addition of thiocyanate or 1,10-phenanthroline, or else by iodometry. If the sample is first reduced chemically, iron can also be determined by titration with permanganate.

Arsenic. The sample is first subjected to reducing conditions to convert arsenic to arsine. The latter is then driven off by heating and absorbed in pyridine containing silver diethyldithiocarbamate. The concentration of the resulting red complex can be determined by measuring its absorbance. Other techniques include the coulometric method of GUTZEIT and a gravimetric method in which all the arsenic present is reduced to arsenic trichloride, which can be distilled off and determined as sulfide.

Sulfur Dioxide. Dissolved sulfur dioxide is determined iodometrically (→ Sulfur Dioxide, Chap. 10.).

Nitrogen Oxides and Nitric Acid. Dissolved nitrogen oxides can be measured by titration with permanganate. Alternatively, the sample may be treated with 1-naphthylamine and sulfanilic acid to convert the nitrogen oxides to an azo dye, which is then determined photometrically. Nitric acid and nitrosylsulfuric acid form a colored species upon addition of brucine, and this can also be determined photometrically.

Chlorides and Fluorides. Chloride is determined gravimetrically by precipitation with silver nitrate. Fluoride can be measured by etching according to the Spielhaczek method.

A wide range of sulfuric acid impurities is now determined on the basis of physical methods; e.g.:

- Mercury, selenium, and arsenic by flameless atomic absorption spectrometry
- Iron, nickel, chromium, zinc, cadmium, lead, copper, vanadium, aluminum, sodium, and potassium by atomic emission spectrography (with inductively coupled plasma) or atomic absorption spectrometry

7.3. Analysis of Acid-Plant Gas Streams

The sulfur dioxide content of contact and tail gases is established by one of the methods described in → Sulfur Dioxide, Chap. 10..

When determining the sulfur trioxide content of sulfuric acid-plant tail gases it is important to bear in mind that residual sulfur dioxide is easily oxidized, which can lead to unrealistically high readings. The following methods give satisfactory results.

The gas sample in question is passed through an aqueous solution of hydrogen peroxide and the resulting sulfuric acid is determined by titration or gravimetric analysis (see above). The fraction of this acid derived from sulfur dioxide is determined by measuring the sulfur dioxide concentration of a second sample and calculating the sulfuric acid equivalent. This is subtracted from the result of the first determination to leave the amount of sulfuric acid due to sulfur trioxide alone.

Alternatively, the gas can be passed through an isopropyl alcohol solution, which absorbs sulfur trioxide without oxidizing sulfur dioxide. The resulting sulfuric acid then is titrated against barium chloride solution using thorin as an indicator [160, 161].

SO_3/H_2SO_4 mists entrained in tail gas are separated in special filters and determined by measurement of the trapped acid. Particle spectra of SO_3/H_2SO_4 mists are determined by means of cascade impactors [162].

8. Sulfur Trioxide

8.1. Properties

Physical Properties. Sulfur trioxide [*7446-11-9*], SO_3, M_T80.06, is the anhydride of sulfuric acid. It is known in all three states of matter. In the gaseous and liquid phases, an equilibrium exists between the monomer, SO_3, and the annular trimer, S_3O_9. This equilibrium is shifted towards S_3O_9 at low temperature. In the presence of slight traces of moisture (ca. 100 ppm H_2O), liquid sulfur trioxide (below ca. 27 °C) and solid sulfur trioxide are transformed into solid polymers, which form asbestos-like, felted crystalline needles. These consist of β-SO_3 and α-SO_3, which are thought to correspond to long SO_3 chains with water saturation at the chain ends – the so-called polysulfuric acids, $HO(SO_2O)_xH$ [163].

Information regarding the physical properties of sulfur trioxide is tabulated in various works [16, 164–166]. The available data originate from different measurements made over the course of the past 60 years, and they are not always mutually consistent, in part because it is extremely

difficult to prepare pure, absolutely anhydrous sulfur trioxide.

Table 2 provides a selection of important physical data. Pure, solid sulfur trioxide, referred to as γ-SO_3, forms silky orthorhombic (ice-like) crystals. The melting points cited for the polymeric forms α-SO_3 and β-SO_3 indicate temperatures at which these solids depolymerize to liquid sulfur trioxide. From an industrial operation standpoint it is important to recognize that the liquid sulfur trioxide originating from α-SO_3 and β-SO_3 exerts a significant vapor pressure: 2.4 bar at 62.2 °C [163].

Table 2. Physical properties of sulfur trioxide

Property	Value	Reference
Gaseous SO_3		
Nominal density, g/L (0°C, 1013 mbar)	3.57	[164]
Specific heat C_p, kJ m^{-3} K^{-1}		
100°C	2.543	[16]
500°C	3.191	[16]
Liquid SO_3		
Density, g/cm^3 (25°C)	1.9	[163]
bp, °C (1013 mbar)	44.8	[164]
Heat of evaporation (boiling point), J/g	538	[163]
Vapor pressure, bar		
20°C	0.26	[166]
30°C	0.47	
50°C	1.32	
100°C	8	[163]
Critical temperature, °C	217.7	[163]
Critical pressure, bar	81.9	[163]
Solid SO_3		
γ-SO_3		
mp, °C	16.86	[163]
Heat of fusion, J/g	119	[163]
β-SO_3		
"Melting point", °C	30.4	[163]
α-SO_3		
"Melting point", °C	62.2	[163]

The temperature dependence of various physical properties of sulfur trioxide has been represented graphically [165]. Formulae have also been worked out from which it is possible to calculate approximate values at any temperature for a number of properties, including vapor pressure, specific heat, and density [163, 167].

Chemical Properties [163, 168]. Because of sulfur trioxide's importance as an industrial intermediate in the production of sulfuric acid, the thermodynamics and kinetics of its generation by the oxidation of sulfur dioxide (Eq. 10) have been extensively studied, as has the reverse reaction. Pure sulfur trioxide is in fact extremely resistant to thermal decomposition because of kinetic inhibition, even at elevated temperatures where thermodynamic equilibrium is shifted heavily toward $SO_2 + O_2$. However, certain catalytically active substances are able to increase the rate of equilibration substantially. In the presence of metals such as platinum [24] or of metal oxides and sulfates (e.g., of iron, copper [169], and, of course, vanadium) the decomposition approaches equilibrium at temperatures above ca. 700 °C.

The sulfur in sulfur trioxide is present in its maximum (hexavalent) oxidation state. Sulfur trioxide is therefore a strong oxidizing agent, and at the same time it is one of the stongest known Lewis acids. This bifunctional reactivity is apparent, for example, in the reaction with hydrogen halides. With hydrogen fluoride, sulfur trioxide reacts as a Lewis acid to form fluorosulfuric acid. Hydrogen bromide and hydrogen iodide, on the other hand, are oxidized under the same conditions to the respective free halogens, while the sulfur trioxide is reduced to give sulfur dioxide or even hydrogen sulfide [163].

Sulfur trioxide reacts at 50 – 150 °C with elemental sulfur to give sulfur dioxide. This reaction is used industrially for the production of pure sulfur dioxide (→ Sulfur Dioxide, Chap. 7.1.). Coke or pulverized coal at elevated temperature will reduce sulfur trioxide to sulfur dioxide, which is the basis for the regeneration step of the Bergbau-Forschung process for flue-gas desulfurization (→ Sulfur Dioxide, Chap. 5.7.2.).

Under absolutely dry conditions, sulfur trioxide is unreactive toward most metals. With metal oxides it reacts at moderately high temperature to form the corresponding metal sulfates. Sulfur trioxide undergoes an extremely violent reaction with water to form H_2SO_4 or higher sulfuric acids. Sulfur trioxide gas reacts instantaneously with wet gases to form sulfuric acid mists, which are extremely difficult to precipitate.

As a general rule, sulfur trioxide reacts very briskly with all organic compounds. In the course of the reaction, the organic compound may be sulfonated, oxidized (decomposed) with the release of water, or dehydrated.

Figure 48. Production of 100 % sulfur trioxide by distillation from oleum
a) Evaporator; b) Heat exchanger; c) SO_3 condenser

8.2. Manufacture

Sulfur trioxide is of course always produced in dilute gaseous form in a contact-process sulfuric acid plant through the oxidation of sulfur dioxide-containing gases. So far, however, the only reported preparation of pure sulfur trioxide from dilute SO_3- containing gases has been a pilot-plant scale process involving cryoscopic condensation [170]. The usual procedure instead involves distillation of oleum. The heat required for oleum distillation is most conveniently supplied by hot contact gas from the associated sulfuric acid plant [171]. Figure 48 shows the method use at Hoechst.

In this approach, 30 – 36 % oleum is preheated indirectly by liquid – liquid heat exchangers and subsequently fed to the top of a falling-film evaporator for distillation. In the evaporator the oleum flows downward as a film on the inner walls of steel tubes that are heated on the outside with hot contact gas in countercurrent. The weak oleum discharged from the evaporator sump, with a residual "free" SO_3 content of 24 – 25 %, is cooled through indirect heat exchange with the entering concentrated oleum, after which it is recycled to the sulfuric acid contact plant for concentration in the oleum tower once again to 30 – 36 %. It is important that the SO_3 content of the oleum not drop below 20 % in the interest of avoiding severe corrosion of the steel tubes at the temperatures prevailing in the evaporator. Sulfur trioxide gas leaving the top of the falling-film evaporator is condensed in a tubular condenser made of steel or aluminum. The cooling water is maintained at ca. 30 °C to ensure that the sulfur trioxide temperature does not fall below 27 °C, since sulfur trioxide would otherwise solidify. The evaporation capacity of the falling-film evaporator is controlled for a particular oleum input rate by adjusting the flow rate of the hot contact gas.

The largest units of this type built so far are designed to produce ca. 3 t/h of SO_3. Apart from falling-film evaporators, forced-circulation evaporators are also used for oleum distillation. In most cases, stainless steel is utilized as the construction material.

8.3. Handling and Uses

When storing and handling liquid sulfur trioxide it is extremely important to prevent polymerization, because any solid formed is very inconvenient to remove. Sulfur trioxide reacts explosively with water, so the vessels must never be cleaned with water. Concentrated sulfuric acid is required for dissolving solid deposits of sulfur trioxide.

In order to maintain sulfur trioxide in the liquid state during storage, tanks and piping must be kept at ca. 30 °C by supplementary heating. Addition of a stabilizer also effectively inhibits the formation of solid polymers at temperatures above the natural solidification point of sulfur trioxide. A number of inorganic and organic compounds are used or have been recommended

as stabilizers, but the extensive patent literature on the subject provides no indication of their mode of action [163].

Liquid sulfur trioxide is among the most dangerous of all industrial materials, and strict safety regulations govern its handling [172, 173]. In the Federal Republic of Germany, for example, every act of transporting liquid sulfur tridioxide over public roads requires a special permit, which can be withdrawn at any time.

Pure sulfur trioxide is used in organic synthesis for sulfonation reactions, including the manufacture of chlorosulfonic acid, thionyl chloride, aminosulfonic acid, dimethyl sulfate, and sulfamide. The reaction is difficult to control if the sulfur trioxide is introduced in liquid form, so it is preferentially supplied as a gas (pure or diluted with an inert gas), as a solution in liquid sulfur dioxide or some other solvent that is inert under the reaction conditions, or as an addition compound with an organic base.

9. Toxicology

Given their high chemical reactivities, it is not surprising that both sulfuric acid and sulfur trioxide have marked toxic and ecological effects [174–176].

9.1. Sulfuric Acid

Effects on Animals. Sulfuric acid has a highly corrosive effect on the eyes, the mucous membranes, and the skin, even in low concentrations. Because it completely destroys living tissue, concentrated sulfuric acid causes burns that penetrate deeply and heal only slowly. Swallowing sulfuric acid produces extreme pain in the digestive tract, vomiting, and shock, and there is a danger of perforation. Sulfuric acid vapors or mists irritate the eyes and the muscous membranes of the nose, pharynx, and respiratory tract, causing heavy coughing and breathlessness. Chronic inflammation of the upper respiratory tract may result, and eventually impairment of the lungs (chronic bronchitis). Even concentrations well below 0.1 vol % (corresponding to ca. 4 g/m^3) will render breathing impossible. Pain and damage to the teeth have also been observed, especially the incisors. The maximum permitted workplace concentration of vapors and mists under German regulations (MAK) is 1 mg/m^3 (ca. 0.245 ppm by volume).

Environmental Effects. Sulfuric acid releases are highly deleterious with respect to ground and surface waters. The substance is toxic to both fish and algae, both directly and as a result of reaction with other materials in the water. Any concentration $\geq$ 1.2 mg/L is considered lethal to fish; 6.3 mg/L or more causes death within 24 h [176].

9.2. Sulfur Trioxide

In principle, sulfur trioxide has the same toxic effects as sulfuric acid [173]. Inhalation of the gas itself or the sulfuric acid mist formed when it comes into contact with humid air causes irritation, burning, and degeneration of the tissue of moist skin, eyes, and mucous membranes, especially in the respiratory tract. This happens relatively rapidly at concentrations $\geq$ 10 ppm by volume. Laryngal edema, chronic bronchitis, and dental damage are possible. In contrast, symptoms of resorptive poisoning have not been observed.

1. Introduction

In 1911, Heike Kamerlingh Onnes discovered that the electrical resistance of mercury abruptly drops to an unmeasurably small value at 4.2 K, and named the phenomenon superconductivity. In the following years, superconductivity was found in many other metals and in a vast number of metallic compounds and alloys. Although the highest known temperature of the transition to the superconducting state (critical temperature T_c) had reached 23 K by 1986, in the majority of cases it was < 10 K. Stable cooling to achieve this so-called conventional superconductivity is possible only with liquid helium, so that the technology is both complex and costly. As a result, the wide adoption of superconductivity in industry has been hindered until now, although a number of special applications (e.g., in magnets, sensors, and microwave electronics) do exist. A comprehensive treatment of the physical properties of conventional superconductivity and some of its industrial applications has appeared in [1].

In 1986, Bednorz and Müller discovered superconductivity at ca. 35 K in an oxide ceramic of composition $(La, Ba)_2CuO_4$ [2]. This discovery initiated a rapid development worldwide, leading to a new class of materials called high-temperature (HT) superconductors, also referred to as ceramic, oxide, or cuprate superconductors. The range of critical temperatures has now been extended up to ca. 133 K. The resulting possibility of maintaining stable superconductivity by cooling with liquid nitrogen (liquid-N_2, 77 K) has led to reconsideration of industrial applications of superconductivity. If some of the initially euphoric predictions (e.g., replacement of high-tension cables by liquid-N_2-cooled superconducting cables) have proved infeasible, many potential industrial applications of HT superconductivity can be perceived, especially in microwave technology and sensors. It will take years, however, to determine the full scope of the potential applications of HT superconductors, and the development of new processes and techniques that take into account the extreme brittleness of these materials will be a crucial step.

In physical terms, superconductivity can be understood only in the context of the quantum mechanics of multiparticle systems (quantum field theory). Furthermore, quantitative predictions require thorough and detailed knowledge of solid-state properties such as electronic band structure and lattice dynamics. Conversely, measurements of parameters in the superconducting state permit inferences about solid-state properties in the normally conducting state. Superconductivity is thus a highly important part of modern solid-state research, as is demonstrated by the awarding of four Nobel prizes in physics (to date) in this field. The 1913 prize went to H. K. Onnes for the discovery of superconductivity; the prize in 1972, to J. Bardeen, L. N. Cooper, and J. R. Schrieffer for their microscopic description of superconductivity (BCS theory); in 1973, to B. D. Josephson for his prediction of quantum coherence effects in two coupled superconductors; and the 1987 prize, to G. Bednorz and K. A. Müller for the discovery of high-temperature superconductivity.

2. Principles

2.1. Electrical Resistance and Thermal Conductivity

An ideal superconductor transports direct electrical current without loss. Although it cannot be proved experimentally that the electrical resistance of a metal in the superconducting state is exactly zero, long-term persistent current experiments with a superconducting ring have shown that the resistance drops by at least 15 orders of magnitude at the onset of superconductivity. The minuscule residual resistance, if any, is thus without detectable consequences.

In contrast, the transport of alternating current always involves losses, even in an ideal superconductor, so that additional cooling power is required. This a.c. resistance of a superconductor increases with increasing frequency ν. For industrially optimized superconductors, itis still some orders of magnitude less than the resistance of (normally conducting) copper or gold at low frequencies (e.g., 50 Hz); only above ca. 100 – 200 GHz do such superconductors exhibit higher a.c. losses.

The thermal conductivity of a superconductor also changes at the onset of superconductivity. For metals in which the contribution of conduction electrons to heat transport dominates the

lattice contribution, the thermal conductivity decreases in the superconducting state. This effect is used in thermal switches, where a bridge made of a superconductor can be switched from the superconducting state ("off") to the normally conducting state ("on") by applying a magnetic field.

2.2. Behavior in Magnetic Fields

When a superconductor is cooled in an external magnetic field, the magnetic field is completely expelled from the superconductor at the onset of superconductivity, except for a surface layer of thickness λ_L (London penetration depth, ca. 10 – 1000 nm). Persistent currents are set in motion in the surface layer, and the magnetic field due to these currents compensates the external field in the interior of the superconductor, which thus behaves as an ideal diamagnetic material.

Figure 1. A ring-shaped magnet is levitated above a liquid-nitrogen-cooled high-temperature superconductor by persistent supercurrents

This Meissner – Ochsenfeld effect can be demonstrated strikingly by the levitation of a permanent magnet. If a small magnet is placed on a warm superconductor, which is then cooled (for example, by pouring LN_2 over it) the magnet is raised up at the onset of superconductivity and remains in a levitated state (see Fig. 1). Because the force levitating the magnet does not involve a time variation of the external field, this behavior cannot be accounted for by induction, which could be explained in terms of classical electrodynamics supplemented by the assumption of ideal conduction. Instead, this effect proves that the superconducting state is a new thermodynamic phase. The Meissner – Ochsenfeld effect allows unambiguous detection of the onset of superconductivity.

With regard to their response to an increasing external magnetic field, two types of superconductors can be distinguished. In type I superconductors, the shielding currents, and thus the free energy of the superconducting state, increase with increasing magnetic field strength until, at a field strength B_c (the thermodynamic critical field), the normally conducting state becomes energetically more favorable. For field strengths $B_a > B_c$, superconductivity is disrupted and, with it, the magnetization M compensating the external field. The field-free Meissner phase abruptly goes over to the normally conducting, field-filled phase (see Fig. 2).

Figure 2. Magnetization curve of a type I superconductor

In a type II superconductor, the Meissner phase exists only up to a field strength B_{c1} (the lower critical field), where $B_{c1} < B_c$. If the external field exceeds B_{c1}, magnetic field in the form of flux filaments (fluxoids) penetrates the material, which remains superconducting. This is the mixed or vortex state. As the magnetic field strength B_a increases further, the surface density of fluxoids increases, so that the magnetization M compensating the external field decreases further until superconductivity collapses at $B_a > B_{c2}$ (upper critical field) and the material enters the normally conducting phase (see Fig. 3).

Figure 3. Magnetization curve of a type II superconductor

B_c, B_{c1}, and B_{c2} are temperature dependent and decrease steadily for $T \to T_c$. Figure 4 presents sample plots of B_c versus T. While the critical fields for type I superconductors are small, the upper critical field strengths B_{c2} in type II superconductors can take on very high values; examples are Nb_3Sn ($T_c \approx 18$ K) up to about 30 T and the high-temperature superconductor $YBa_2Cu_3O_7$ ($T_c \approx 92$ K) up to 100 T. Therefore, superconductors potentially suitable for technical applications are almost exclusively of type II.

Figure 4. Thermodynamic critical field $B_c(T)$ for the elements Al, Sn, Hg, and Pb

The mean free path l of conduction electrons is a decisive parameter for the occurrence of type II superconductivity. If l is diminished in a type I superconductor (e.g., by incorporation of defects or by alloying with a second material), the transition to type II superconductivity takes place at a certain value of l. Most alloys and intermetallic compounds are therefore of type II; high-temperature superconductors represent the extreme case.

The magnetic flux penetrating a superconductor must be an integer multiple of the elementary fluxoid quantum $\Phi_0 = h/2e$, where h is Planck's constant and e is the elementary charge; Φ_0 is ca. 2×10^{-15} Wb. This flux quantization follows directly from the quantum coherence of the superconducting state; the appearance of twice the elementary charge $2e$ in Φ_0 indicates that electron pairs are the superconducting charge carriers (see Section 2.6). Each of the fluxoids in the mixed state carries exactly one fluxoid quantum.

Flux quantization can be quantitatively proved with small superconducting rings in which a persistent current has been induced.

2.3. Critical Current

The existence of a critical magnetic field, beyond which superconductivity is disrupted, directly implies the existence of a critical current (because of the intrinsic magnetic field generated by this current). Accordingly, each superconductor has a maximum transport current I_c that it can carry. This critical current is of central importance for industrial applications. It depends on the material properties and the geometry of the superconductor, the temperature, and the strength of any applied external magnetic field. Because the critical fields B_c, B_{c1}, and B_{c2} become smaller as the temperature rises and vanish for $T \geq T_c$, critical currents exhibit a corresponding temperature dependence.

Because type I superconductors have relatively low critical fields, they also have little current-carrying capacity. For example, a lead wire 1 mm in diameter has $I_c \approx 200$ A at $T = 0$ K. This value is easily derived, since the transport current flowing through the wire must generate at the surface of the wire a magnetic field with B_c (Pb) ≈ 80 mT.

Many type II superconductors have very high (upper) critical fields, which imply very high critical currents. This gives rise to a new problem that does not exist for type I superconductors.

Due to the transport current, the fluxoids penetrating the superconductor in the mixed state experience a Lorentz force, perpendicular to the plane spanned by the transport current and the fluoxid. If the fluoxids are free to move, they begin to do so. This flux movement is associated with energy dissipation and leads to a finite resistance. Only if the fluxoids are pinned at traps can their movement be prevented or reduced. Traps include lattice defects and normally conducting inclusions. Type II superconductors with good flux pinning are said to be "hard". Conventional superconductors optimized in this way, such as Nb_3Sn or NbTi, achieve critical current densities (the critical current I_c divided by the conductor cross section) J_c of $10^9 - 10^{10}$ A/m^2 at $T = 4.2$ K.

Figure 5. Critical current densities J_c (B) for selected superconductors
a) Bi-2212 tape at 4.2 K (B parallel to tape); b) $PbMo_6S_8$ wire at 4.2 K; c) Nb_3Sn at 4.2 K; d) Y123 specimen at 77 K (B parallel to CuO_2 planes) e) NbTi-50 at 4.2 K; f) Bi-2223 tape at 77 K (B parallel to tape);
All commercial helium-cooled high-current superconductors lie in the shaded area.

In liquid-N_2-cooled HT superconductors, flux movement (sometimes referred to as flux creep) is more prominent because of the higher operating temperature and the fundamentally poorer pinning properties of HT superconductors, which result in increased thermal activation of the fluxoids away from their traps. The phenomenon is especially marked for bulk HT superconductor specimens, where the J_c ($T = 77$ K) values attainable at present are only 5×10^8 to 2×10^9 A/m^2, depending on the material, despite the high B_{c2} values; a further drastic reduction occurs in an external field. In contrast, epitaxially grown HT superconductor films with thicknesses up to a few hundred nanometers exhibit J_c ($T = 77$ K) values up to almost 10^{11} A/m^2. The highly effective pinning mechanism in these thin layers has not yet been elucidated. Figure 5 shows the critical current density J_c as a function of external magnetic field for some conventional and high-temperature superconductors.

2.4. Energy Gap and Thermodynamic Properties

Absorption experiments performed with light or acoustic waves show the existence of an energy gap $2\,\Delta$ in the excitation spectrum of superconducting electrons. These electrons can absorb energy from the light or sound wave only when the quantum energy $h\nu$ associated with the frequency ν exceeds $2\,\Delta$ ($h\nu \geq 2\,\Delta$). The existence of this energy gap is due, in turn, to the quantum coherence of the superconducting state. It is roughly proportional to the critical temperature; according to the BCS theory (see Section 2.6)

$$2\,\Delta\,(T = 0) = 3.52 k_B T_c \tag{1}$$

where k_B is the Boltzmann constant.

The most precise way to measure the energy gap is to use the quantum-mechanical tunneling effect. Two superconducting electrodes are separated by a very thin (ca. 1 nm) insulating barrier, and the current – voltage characteristic is measured (Fig. 6, see next page). Because of their wave nature, single electrons can pass through the potential barrier even though the laws of classical mechanics forbid this. Accordingly, if a voltage U is imposed between the electrodes, a (tunneling) current I may in principle flow across the barrier. Provided the two electrodes are normally conducting, the result is a linear characteristic (ohmic behavior). If, however, they are in the superconducting state, the tunnel-

Figure 6. Circuit for measuring the I versus U characteristic of a tunnel diode
SC = Superconductor; I = Insulator

ing current can only flow when a tunneling electron extracts the minimum energy $2\,\Delta$ from the electric field (i.e., $eU \geq 2\,\Delta$). Rigorously, this holds only at $T = 0$. For $0 < T < T_c$, some normally conducting electrons (thermally dissociated Cooper pairs) are always present and contribute to the current even below the threshold voltage $U = 2\,\Delta/e$ and thus cause some smearing of the initially sharp threshold (see Fig. 7). If one of the electrodes is replaced by normally conducting material, a tunneling current can flow above half the threshold voltage ($U = \Delta/e$).

Figure 7. Qualitative curve of I versus U recorded with the circuit of Figure 6
a) Ohmic curve; b) Curve for $T = 0$; c) Curve for $0 < T < T_c$

Figure 8. Temperature dependence of the energy gap for tantalum, determined by tunnel measurement

The transition of a material from the normally conducting to the superconducting state, as occurs on cooling with no applied magnetic field, is a second-order transition. No latent heat accompanies it, and the order parameter, which is the energy gap $2\,\Delta\,(T)$, vanishes steadily as $T \to T_c$. Figure 8 illustrates this behavior for the example of tantalum.

The specific heat $c_v\,(T)$, in contrast, changes abruptly at $T = T_c$. Below T_c, the electron contribution falls off exponentially as a direct consequence of the widening energy gap (Fig. 9). The jump in $c_v\,(T)$ results from the condensation of electrons into pairs at $T < T_c$ (see Section 2.6).

Figure 9. Specific heat $cv\,(T)$ for tin (open circles) with superconductivity suppressed by an applied magnetic field (solid circles)

The associated condensation energy, which is the difference in free energy between the normally conducting and superconducting states, is given by

$$\Delta F = F_{\mathrm{n}} - F_{\mathrm{s}} = V H_{\mathrm{c}}^2/8\pi \tag{2}$$

where B_{c} is the thermodynamic critical field defined in Section 2.2, V is the specimen volume and H_{c} is the critical magnetic flux density. For type I superconductors, ΔF can be obtained directly from B_{c}; calorimetric measurements are required for type II superconductors.

2.5. Josephson Effects

The $I(U)$ curve shown in Figure 7 describes only the current represented by the sum of tunneling currents of individual electrons. JOSEPHSON predicted in 1962 that electron pairs could tunnel through the barrier between two superconductors provided the junction is sufficiently thin. In other words, an additional supercurrent can flow across such a Josephson junction (with $U = 0$). This d.c. Josephson effect has since been confirmed experimentally.

The Josephson current is extremely sensitive to external magnetic fields, and the structure of this relationship is governed by the elementary fluxoid quantum Φ_0. Figure 10 shows the maximum Josephson current as a function of the external field for a tin – tin oxide – tin junction. The experimental curve resembles the intensity pattern for a wave diffracted at a slit. In fact, this phenomenon can be described in terms of the interference of two coherent quantum states in the two weakly coupled superconductors, with the magnetic field determining the phase shift between the two states. The strong magnetic field dependence of the Josephson current is employed in the design of extremely sensitive magnetic field sensors called SQUIDs (superconducting quantum interference devices; see Chap. 4).

If a voltage drop U is imposed across a Josephson junction, an additional alternating current occurs whose frequency is given by

$$\nu_{\mathrm{J}} = 2eU/h \tag{3}$$

For $U = 1$ mV, $\nu_{\mathrm{J}} = 4.85 \times 10^{11}\ \mathrm{s}^{-1}$. Because frequency can be measured with very high accuracy, this a.c. Josephson effect offers a way of constructing voltage standards by connecting many Josephson junctions in series.

Figure 10. Critical Josephson current $I_{\mathrm{c}}(B)$ of aSn/SnO_x/Sn tunnel electrode plotted versus applied magnetic field

2.6. Theoretical Descriptions

In 1934, GORTER and CASIMIR devised a phenomenological theory that treats normally conducting and superconducting electrons as two fluids that interpenetrate without friction. This simple approach describes very well the temperature dependence of the condensation energy, and hence of the thermodynamic field. In 1935, F. and H. LONDON improved this two-fluid theory by postulating the London equation, which supplements Maxwellian electrodynamics by describing the Meissner – Ochsenfeld effect. In a nonlocal generalization of this theory, PIPPARD (1953) first introduced the notion of coherence (see below). In 1950, GINSBURG and LANDAU proposed an extension of the London theory that also permits local variation of the superconducting electron density; this concept was later stated in concrete terms by ABRIKOSOV and confirmed on a microscopic scale by GORKOV. Today the Ginsburg – Landau or GLAG theory is employed chiefly for the quantitative treatment of position-dependent phenomena in type II superconductors (e.g., calculating the spatial structure of a fluxoid).

In 1957, BARDEEN, COOPER, and SCHRIEFFER published their microscopic theory of superconductivity (BCS theory). The key assumption is pair formation: two electrons having opposite

momentum and spin form a Cooper pair. By the Pauli exclusion principle, these pairs are closely correlated with one another and condense into a coherent (macroscopic) quantum state with a single phase and a single amplitude, in which all the electrons have lost their individual degrees of freedom. This BCS state accounts for the Meissner – Ochsenfeld effect as well as the vanishing of the electrical resistance; it yields formulas for the temperature dependence of many parameters, such as energy gap $2\Delta(T)$, penetration depth $\lambda(T)$, and nuclear spin relaxation rate $\alpha(T)$, in quantitative agreement with experiment (see, for example, Fig. 8).

The prerequisite for pair condensation is the existence of an attractive interaction between the electrons. If this has strength V and the state density of electrons at the Fermi energy is given by $N(\varepsilon_F)$, the BCS theory gives the following expression for the transition temperature T_c of the superconductor:

$$T_c = 1.14\Theta \exp\left[-1/N(\varepsilon_F)\,V\right] \tag{4}$$

where $k_B\Theta = \omega_c$ is the energetic range of the interaction V. For the energy gap $2\Delta(T=0)$, Equation (1) gives a value of $3.52\,k_B T_c$.

Because electrons have like charges and therefore repel each other, the attraction required for pair condensation can arise only from a polarizable background medium. As early as 1950, Fröhlich proposed that the positively charged lattice of atomic residues could act as such a medium. Because in this model the electrons interact via lattice vibrations (phonons), the resulting coupling is referred to as electron – phonon coupling. The temperature scale Θ is then a characteristic phonon temperature, approximately equal to the Debye temperature Θ_D of the superconductor.

The BCS theory is rigorously valid only in the limiting case of weak coupling where $N(\varepsilon_F)\,V << 1$. Eliashberg formulated an extension of the BCS theory for strong electron – phonon coupling, which leads to material-specific corrections, mostly small, in the respective formulas. Numerous experiments have shown that virtually all conventional superconductors (see Chap. 3) can be described by the Eliashberg theory.

The first attempts to apply the Eliashberg theory to the high-temperature superconductors were unsuccessful. Several alternatives were proposed, involving either non-BCS states or a coupling mechanism other than conventional electron – phonon coupling. The controversy over the correct theoretical description of HT superconductivity continues, but there are clear experimental indications (flux quantization, Josephson effects) that the ground state of high-temperature superconductors is a coherent pair state [3].

The superconducting state is coherent only in a finite volume with a linear dimension, known as the coherence length ξ. For type I superconductors and $T = 0$, ξ is a few hundred nanometers; for conventional type II superconductors, a few tens of nanometers. High-temperature superconductors display strongly direction dependent ξ with values of 0.2 – 2 nm. These very small coherence lengths are a major drawback for industrial applications, because they result in high sensitivity to impurities and defects as well as strongly reduced trapping forces for fluxoids.

A thorough presentation of the theory for conventional superconductors can be found in [4], and a survey of theoretical models proposed for high-temperature superconductivity, in [5].

3. Classes of Superconductors

Many thousands of superconductors are known at present, including metallic elements, alloys, intermetallic compounds, and compounds with nonmetallic components. The rigorous classification of these materials is often difficult and to a degree arbitrary. The cuprate-based oxide superconductors discovered in 1986, however, can be delimited relatively well. Because many of them have $T_c > 77$ K, they are generally referred to as high-temperature superconductors (see Section 3.3).

Another relatively well defined class comprises organic superconductors, which were discovered in 1980 and by the early 1990s T_c values up to ca. 13 K had been attained (see Chap. 6).

By far the largest class is composed of the conventional or classical superconductors (Section 3.1). It includes all superconducting elements and alloys, as well as many intermetallic compounds and metal – nonmetal compounds such as hydrides, sulfides, oxides, and

nitrides. The maximum T_c for this group is 23 K (Nb_3Ge), but most members of the class have $T_c < 10$ K, so that helium cooling is required.

The term "exotic" superconductors (Section 3.2) includes all superconducting materials that cannot be easily assigned to the conventional, organic, and high-temperature superconductors.

While the coupling mechanisms responsible for superconductivity in most of these exotic compounds are as unclear as those involved in high-temperature superconductivity, electron–phonon coupling can be assumed for classical superconductors almost without exception.

3.1. Classical Superconductors

Elements. Twenty-nine pure metals are known to be superconductive at normal pressure (Table 1). A number of other elements exhibit superconductivity only in high-pressure phases; these in clude some metals (Ba, Ge, Sc) but also elements such as P and Se that are nonmetallic at normal pressure and enter metallic phases only at high pressure. It is possible that still further metallic elements (alkali metals or noble metals, for example) become superconductive under normal pressure if they are cooled sufficiently. Superconductivity in rhodium, for instance, was not discovered until 1982 when the critical temperature of $T_c \approx 325\,\mu$K was attained by using a complicated cryogenic technique [6].

It is, however, certain that not every pure metal becomes superconducting at a sufficiently low temperature. The main counterexamples are the ferromagnetic elements Fe, Co, and Ni. No coexistence has ever been observed between superconductivity and inherent ferromagnetism, and this is in fact a theoretical impossibility for a BCS superconductor. While the BCS ground state requires the spins in the electron pair to be

antiparallel (see Section 2.6), ferromagnetism is based on parallel spin of conduction electrons, so that ferromagnetism breaks up pairs and interferes with superconductivity. Accordingly, superconductivity is excluded for the ferromagnetic elements, Fe, Co, and Ni, even at absolute zero.

Industrial Superconductors. Only in a few cases are pure metals suitable for applications; examples are Nb in SQUID technology and Pb in heat switches. Conventional industrial superconductors are generally alloys or stoichiometrically sharply defined compounds; all are of type II. For specific technical requirements, they must be optimized in the following respects:

1) High critical temperature: $T_c \geq 10$ K for stable cooling with liquid He^4 (4.2 K)
2) High critical current density: J_c (4.2 K) $\geq 10^8 - 10^{10}$ A/m^2, especially for applications in power engineering and microelectronics
3) High critical magnetic field: B_{c2} (4.2 K) $\geq 10 - 20$ T for use in magnets
4) Good mechanical properties: ductility, elasticity, and tensile strength

Of the four points, the last is most critical. Superconducting materials display a tendency to become more brittle the higher their transition temperature, and this is also true of high-temperature superconductors. The processing of industrial superconductors thus entails complicated techniques.

Apart from niobium, the most important conventional industrial superconductors are the alloy NbTi50 and the A15 compound Nb_3Sn. In addition, the Chevrel phase $PbMo_6S_8$ and the hard material NbN have some application potential for the future. Table 2 lists important data for these materials. NbTi50 stands out by virtue of its ductility; at present it is the most widely used industrial superconductor.

3.2. Exotic Superconductors

Heavy-Fermion Superconductors. Superconductivity below $T_c \approx 0.6$ K in the compound $CeCu_2Si_2$, discovered in 1978, is due to the condensation of very heavy electrons with effective masses around 300 times the free electron mass. Similar behavior is observed in some uranium compounds, such as UBe_{13} ($T_c \approx 0.9$ K), UPt_3 ($T_c \approx 0.45$ K), and UAl_2Pd_3 ($T_c \approx 2$ K) [7]. Although technically unpromising, these systems are of major interest for modern solid-state physics. Both the symmetry of the superconducting ground state and the effective pair-formation mechanisms remain largely unclear.

Polymeric Sulfur Nitride. The first superconducting polymer, $(SN)_x$, was discovered in 1973. It consists of long chains collected into bundles. The gold-colored, lustrous material is metallically conductive along the chains and becomes superconducting at $T_c = 0.26$ K. It exhibits highly anisotropic behavior in a magnetic field. $(SN)_x$ is practically a one-dimensional conductor [8].

Fullerenes. In 1991 superconductivity was discovered in alkali-metal-doped fullerene crystals of composition A_3C_{60} (A = K, Rb, Cs) [9]. Figure 11 shows the relatively simple cubic structure of these crystals. The compounds have high transition temperatures (18 K for K_3C_{60}, 28 K for Rb_3C_{60}, 33 K for Cs_2RbC_{60}). Undoped C_{60} crystals are insulators, and A_3C_{60} exhibits metallic behavior and hence superconductivity only when the alkali metal atoms donate valence electrons to the narrow conduction band, which then becomes half-filled. The high T_c values can readily be accounted for within the BCS theory on the basis of electron – phonon coupling. They result from a high Debye temperature (due to the small size of C atoms) combined with a relatively high electron-state

density (narrow conduction band). Alkali-metal-doped fullerenes react vigorously with oxygen and moisture and so cannot be employed in industry.

Figure 11. Crystal structure of the superconducting fullerene compound K_3C_{60} (large solid circles represent K atoms)

Because of their close relationship to alkali-metal-doped graphites, which can also become superconductive, it does not appear appropriate to classify these materials with the organic superconductors.

Doped Oxide Semiconductors. Some oxide semiconductors exhibit superconductivity after they have been rendered metallic by doping. These compounds include $SrTiO_3$ and $BaBiO_3$, both having perovskite structures, as well as $Li_{1+x}Ti_{2-x}O_4$ with a spinel structure. The highest T_c values found up to now in these three classes are ca. 0.7 K ($SrTi_{1-x}Nb_xO_3$, $x \approx 0.01$) [10], ca. 12 K ($LiTi_2O_4$) [11], and ≈ 30 K ($Ba_{0.7}K_{0.3}BiO_3$) [12]. All these superconductors have very low concentrations of free charge carriers (ca. 10^{18} to $10^{20}\,cm^{-3}$), sharing this property with high-temperature superconductors as they do a metal – insulator transition and the perovskite-like structure. Especially in view of the very high transition temperature of $BaKBiO_3$, a relationship to high-temperature superconductors is thus a plausible supposition. However, the two-dimensional structures (CuO_2 planes) typical of HT superconductors are absent, as is magnetic order in the undoped, insulating substances.

3.3. High-Temperature Superconductors

Structure. Structurally, all high-temperature superconductors are perovskite derivatives. Important building blocks are CuO_6 octahedra, which may degenerate to CuO_5 pyramids or CuO_4 squares as a result of oxygen deficiency. Linked together at the corners, these units form CuO_2 planes, which are either isolated from one another by (oxide) planes of other elements (single-layer structures) or arranged in packages of two or three layers. It is certain that these CuO_2 planes are crucial determinants of the physical properties of the materials, and hence of their superconductivity. All other components serve to stabilize the structure or provide a charge reservoir. Figure 12 illustrates the three-layer structure of Tl-2223 ($T_c \approx 125$ K).

Figure 12. Crystal structure of the high-temperature superconductor Tl-2223 ($T_c \approx 125$ K)

(*x*, *T*) Phase Diagram. Each HT superconductor has a reference compound that is insulating and antiferromagnetic and from which it is derived by *n*- or *p*-type doping. Examples are $La_{1.85}Sr_{0.15}CuO_4$ and $YBa_2Cu_3O_7$, which are obtained from the compounds La_2CuO_4 and $YBa_2Cu_3O_6$ by *p*-type doping, and the *n*-doped HT superconductor $Nd_{1.85}Ce_{0.15}CuO_4$ ($T_c \approx 20$ K), which can be derived from Nd_2CuO_4. All known superconductors with $T_c > 40$ K are *p*-doped.

The effect of doping on the physical properties of a high-temperature superconductor is illustrated by the (x, T) phase diagram of $La_{2-x}Sr_xCuO_4$ (Fig. 13). Qualitatively, this plot also applies to other HT superconductors. Undoped La_2CuO_4 is an insulator and exhibits antiferromagnetism, which decays rapidly as x increases; there is an insulator – metal transition at $x \approx 0.04$, above which the system becomes paramagnetic and superconducting. T_c is a maximum for $x \approx 0.15$, falling off again from that point on and vanishing beyond $x \approx 0.3$.

Figure 13. (x, T) Phase diagram of $La_{2-x}Sr_xCuO_4$
AF = Antiferromagnetic phase; SG = Spin-glass behavior; S = Superconductivity

High-Temperature Superconductors with $T_c > 77$ K. The most important families of superconductors with $T_c > 77$ K (nitrogen cooling) are listed in Table 3. A more comprehensive list can be found in [13].

Among these compounds, Y123, Bi-2212 and Bi-2223, and Tl-2223 are most significant for industrial applications at present.

Table 3. High-temperature superconductors with $T_c > 77$ K

Formula	Short hand	Maximum T_c
$REBa_2Cu_3O_7$*	REBCO or 123	92 K (YBCO)
$Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ (+ Pb doping)	BSCCO or Bi-22(n−1)n	90 K (Bi-2212) 122 K (Bi-2223) 90 K (Bi-2234)

$Tl_1A_2Ca_{n-1}Cu_nO_{2n+3}$ (A = Sr, Ba)	Tl-12(n−1)n	90 K (Tl-1212) 122 K (Tl-1223) 122 K (Tl-1234) 110 K (Tl-1245)

* RE = Rare earth.

HT superconductor specimens prepared as ceramics (e.g., sintered from mixed oxides) have critical current densities J_c ($T = 77$ K) $< 10^7$ A/m^2 and are thus unsuitable for most applications. The low J_c values result from grain boundaries, which can be eliminated or reduced by special fabrication methods, so that J_c can be substantially increased. Two methods are generally used:

1) Epitaxial films: this method is based on the epitaxial growth of a high-temperature superconductor film on a single-crystal substrate having an appropriate crystal structure (e.g., $SrTiO_3$ or Al_2O_3). Frequently used deposition methods are laser ablation, sputtering, and MOCVD (Metal Organic Chemical Vapor Deposition). High current densities are obtained for epitaxial films with the CuO_2 planes parallel to the substrate surface. This technique is used chiefly in the fabrication of Y123 and Tl-2223 films for use in microwave electronics and sensor systems. Critical current densities up to ca. 7×10^{10} A/m^2 are observed in Y123 films at $T = 77$ K; the film thicknesses are some hundreds of nanometers [5].
2) Textured bulk materials: preferred orientation of the crystallites (texture) and the consequent reduction in grain boundaries are essential for achieving high current densities in bulk HT superconductor materials. For Y123, texture is produced by cooling the melt in a temperature gradient and/or in a strong magnetic field (melt texturing). In this way, it is possible to obtain bars or disks weighing up to hundreds of grams and offering

good flux pinning and J_c ($T = 77$ K) values up to ca. 10^9 A/m^2; the potential for these materials lies primarily in the area of passive magnetic bearings [5]. The main materials used in making wires and tapes are Bi-2212 and Bi-2223, which is cladded in silver and subjected to a complicated sequence of rolling and pressing steps as well as tempering stages. Texturing in these cases is apparently promoted by mechanical working. Bi-2212 tapes made in this way are suitable for use only with helium cooling, but they exhibit outstanding current-carrying capacities even in very strong magnetic fields: J_c ($T = 4.2$ K, $B_a = 25$ T) $\approx 2 \times 10^9$ A/m^2. Bi-2223 tapes, in contrast, are better suited to use with LN_2 cooling: J_c ($T = 77$ K) $\approx 5 \times 10^8$ A/m^2 at zero field. An applied external field does, however, lead to a drastic reduction in J_c, which can be attributed to inadequate flux pinning in this material (flux creep; see Section 2.3) [5].

4. Electronic Applications of Superconductivity

Superconducting electronics [14–17] have already become an indispensable resource for physical measurement and detection, for ultrafast "super" logic chips, for many high-frequency applications, and for certain calibration purposes. These circuits are used where very low noise, very high sensitivity, minimal losses, short switching times, and stability of voltage calibration are crucial. Advantages over competing semiconductor devices include the macroscopic quantum effects of superconductivity (Josephson effects), unparalleled low noise levels, and novel effects such as quantum interference and voltage-frequency conversion governed solely by physical constants. In such applications, superconducting components are employed in the most critical areas of physical instrumentation, ultrafast logic circuits, and high-frequency engineering, and also find use as voltage standards. Because cooling is always desirable when minimal noise is desired, superconducting electronics represents the technology of choice under extreme requirements, particularly in research and in military hardware. Helium-cooled SQUID systems have become firmly established in laboratories, where they serve as extrasensitive magnetometers and susceptometers and as instruments for measuring derived quantities.

The need for cooling to temperatures below T_c was long considered a major drawback and prevented the adoption of superconducting electronics in conventional hardware. Even where superconducting devices surpassed all competition (or where there was no competition in the first place), as in biomagnetic medical diagnostics using SQUID arrays, the cost of cooling and shielding has presented a major obstacle to the commercial success of superconducting electronics.

Important milestones in the commercialization of superconducting electronics include the transition to competitive electronics based on high-temperature superconductors and the rapid progress made recently in the development of cooling equipment for electronics, especially the pulse-tube cooler.

4.1. Superconductivity Effects Important for Electronic Applications

4.1.1. Pure Inductances

In a superconductor d.c. current transport remains virtually lossless up to frequencies in the megahertz range (see Section 2.1) [losses comparable to copper are observed only at 100 GHz in niobium at 4 K or in YBCO (yttrium barium copper oxide) at 77 K], provided two conditions are met:

1) The magnetic field amplitudes must be sufficiently small that no flux penetrates into the superconductor
2) Flux "frozen in" by the cooling process must not be able to migrate (i.e., it must be pinned)

These requirements can be satisfied in electronic applications. Two important applications of the effect are therefore possible: shielding of (cryo)electronic circuits and lossless "transformation" of magnetic flux from zero frequency up into the megahertz range. In the design of these applications, the superconducting structure can be treated as a simple equivalent circuit composed of ideal inductances and capacitances with

no resistive components. If the capacitances are negligible, the integrated Faraday induction law

$$n_1 \Delta\Phi_1 = -I \Sigma L_i$$

describes a "flux transformer" comprising a closed series circuit of inductances L_i; when the flux in L_1, having n_1 turns, changes by $\Delta\Phi_1$, a current I is induced in the circuit. This current I acts to oppose the flux in L_1, and if the L_i have been properly selected it will displace flux from L_1 to the L_i as desired. The L_i can, of course, be any extended structures, not just coils.

Within the stated constraints, this flux transformation is independent of frequency. The effect has proved extremely useful for transmitting magnetic flux from a field pickup to a magnetic flux sensor. It is also important in the construction of flux concentrators/transformers for SQUID applications ranging from simple susceptometers to gravity-wave detectors and monopole detectors [14, pp. 178 – 190], [17, pp. 388 – 404].

If there is no inductive load ($L_i = 0$ for $i > 1$), L_1 provides ideal shielding of external flux changes. This principle can be employed for creating volumes practically free of magnetic fields by "inflating" an initially folded superconducting pouch [17, pp. 354 – 359].

4.1.2. Small High-Frequency Losses

In superconducting materials, electrical losses vanish if the current densities $J < J_c$ are constant over time. The losses at small high-frequency power increase as a function of f^2 but still remain very low over a wide frequency range. For the best epitaxial YBCO films, the surface resistance R_s (77 K) at 100 GHz is always an order of magnitude smaller than in cooled copper. Figure 14 illustrates this point, comparing $R_s(f)$ for high-quality YBCO films with the surface resistance of copper. At a given frequency, losses increase rapidly above a high-frequency power threshold, corresponding to a magnetic field amplitude of ca. 0.03 T, beyond which flux penetrates into the superconductor (see Section 2.2). Signal propagation in superconductors is nearly dispersionless below $f/\text{GHz} = 73\, T_c/\text{K}$, so that this effect can be utilized for high-rate information transmission.

Figure 14. Measured surface resistance together with calculated and measured strip-line losses [28] for YBCO and copper at 77 K (dielectric losses not included)
a) Copper strip line at 300 K; b) Copper strip line at 70 K; c) Copper; d) RG-9 coaxial cable; e) Copper strip line at 77 K (measured); f) Epitaxial YBCO; g) YBCO strip line at 77 K (theoretical); h) YBCO strip line at 27 K (theoretical); i) Atmospheric propagation at sea level

Superconducting high-frequency resonators (cavities) and low-loss delay lines and filters for frequencies up to 100 GHz used to be important only in military hardware (special radar techniques). High-temperature superconductors are now permitting use in civilian areas: remote sensing of the Earth, mobile radio, and civilian radar (see Section 4.3.4).

4.1.3. Energy-Gap Effects

Superconductor – insulator – superconductor (SIS) tunnel junctions are used for extremely low-noise direct ("video") or heterodyne detection of millimeter radiation in radio astronomy (see Section 2.4 and Figs. 6 and 7). These devices are operated at temperatures well below T_c. Josephson effects are purposely suppressed by a static magnetic field. The devices utilize two effects: first, the extreme nonlinearity of the current – voltage characteristic for SIS junctions made with low-temperature superconductors (abrupt change in tunneling current at the total energy gap); second, the quantum effect of photon-assisted tunneling. With helium-cooled Pb/Bi/In oxide – Pb/Bi tunnel junctions, the quantum limit (cutoff) of the mixer noise temperature $T_M = \hbar\omega/2k_B$ (where $\hbar = 1.0546 \times 10^{-34}$ Js) has been reached for detection in the 100 GHz range; this makes the technique indispensable in radio astronomy [14, pp. 259 – 284]. The state of the art is an integrated submillimeter low-temperature superconductor detector

circuit like the one built at Chalmers University of Technology in Göteborg, Sweden [18]. It does not appear desirable to replace low-temperature with high-temperature superconductors in this case, since as yet no SIS tunnel junction has been devised on the basis of HT superconductors.

4.1.4. Quantum Interference Effects

The coherence property of the superconducting state is discussed in Sections 2.5 and 2.6. Because Cooper pairs "overlap" within the coherence length and in this way the coherence property is propagated, macroscopic structures of superconductors exhibit macroscopic interference phenomena (Section 2.5, Fig. 10). The magnetic flux enclosed by a macroscopic (e.g., on the scale of millimeters) superconducting ring is quantized; this can be understood as the constructive interference of Cooper-pair waves with a multiple of 2π phase difference along the ring, so that the magnetic flux enclosed by the superconducting ring is a corresponding multiple of the magnetic fluxoid quantum $\Phi_0 = h/2\varrho = 2.0679 \times 10^{-15}\,\mathrm{Tm}^2$. The Josephson junctions discussed below make it possible to introduce magnetic flux into a superconducting ring in continuous fashion and to utilize the macroscopic quantum interference in the ring for measurement purposes (the basis of SQUID devices). Magnetic-field-controlled quantum interference in a Josephson junction is discussed above (Section 2.5, Fig. 10). In accordance with the ratio of areas, external magnetic fields act much more strongly on quantum interference in the macroscopic ring (area $> 1000\,\mu\mathrm{m}^2$) than on quantum interference in a single Josephson junction enclosing less than $1\,\mu\mathrm{m}^2$ of the field. For applications with magnetic control, Josephson junctions optimized with respect to noise level and switching time are purposely made small ("point" contacts) and are linked with well-defined superconducting interferometer ring structures.

4.2. Josephson Junctions, Tunnel Junctions, and Weak Links

4.2.1. Junction Types and Their Significance

The Josephson junction is the essential nonlinear component in superconducting electronics. Figure 15 illustrates the basic current – voltage (I/U) characteristics of Josephson junctions. Such an element can be modeled by a parallel network of a Josephson junction, an ohmic resistance or SIS tunnel characteristic (Section 2.4, Fig. 7), and a capacitance, where the I and U

Figure 15. Ideal current – voltage characteristics of the Josephson junction
A) Steady behavior; B) Switching behavior
N = Normal conductor ; S′, S = Superconductor

values of the Josephson junction are related to each other and to time by the Josephson equation

$$I = I_c \sin(\delta_0 + 2eUt/h)$$

where I_c is the critical current, δ_0 the phase offset related to the "frozen in" flux, and h is Planck's constant.

The characteristic of Figure 15 A is a time average and is steady; that of Figure 15 B exhibits switching behavior. The transition between Josephson current and quasiparticle current, which can take place on a picosecond time scale, long formed the basis for all major logic applications of superconductivity, with the Josephson threshold-value switch as active element and with I_c as threshold value. The "weak-link" characteristic (Fig. 15 A) is well-suited to sensor (SQUID) applications and new logic circuits of RSFQ type. Characteristic 15 A can (but need not) be derived from 15 B by bridging with a resistance; 15 A simply presupposes a weak coupling between the superconductors S, not the existence of a tunnel junction. Characteristic 15 A may arise if the two superconductors S are connected by a normally conducting bridge or a bridge made up of a "weakened" superconductor. For quantum coherence to be preserved between the superconductors S, the bridges must have dimensions comparable with the superconducting coherence length in the bridge material. For well-characterized tunnel junctions, the noise properties can be theoretically described in an acceptable manner (to within a factor of two to three); for bridges, deviations of up to two orders of magnitude can occur, so that large-scale integrated circuits have not been feasible up to now [19]. So far, Josephson junctions made of high-temperature superconducting materials, which can be operated successfully at elevated temperature (ca. 70 K), have all been of type 15 A.

4.2.2. Josephson Circuits, Digital Circuits, Digital Signal Processing, and Voltage Standards

Circuits containing Josephson junctions and superconducting current paths forming closed structures are interferometers of the SQUID type and are discussed in Section 4.2.3. As current-driven switches, they have found some use in logic circuits and A/D converters as well. Important switching elements for Josephson circuits, besides the Josephson junctions proper, are thin-film resistors, microstrip lines (select lines, bias lines), and connections formed by superconducting current paths on a substrate coated with a dielectric film. Various types of latching logic gates, ranging from a relatively large-area interferometer to the very compact gates in four-junction logic, and a variety of gate families and memory cells have been devised; these have been developed to LSI (large-scale integrated) complexity, particularly in Japan [15, pp. 1 – 20], [16, pp. 101 – 134]. The crowning achievement in this line is a functioning four-bit microprocessor running at 770 MHz. The state of the art comprises superconducting structures of niobium or NbN with tunnel barriers of aluminum oxide. The mean power consumption of a logic gate in this technology is ca. 10 μW at 4 K. Despite advanced niobium technology, there is as yet no satisfactory solution for superconducting fast-access mass storage, and indeed no solution is in prospect. This defect might be remedied with a superconducting shift register as working memory, with hybrid combinations employing cooled CMOS (complementary metal oxide Silicon) semiconductor mass memory; such an approach is being pursued in Japan and the United States. A more ambitious and promising technique is being explored in the United States: the nonlatching rapid single flux quantum (RSFQ) logic family employing niobium superconductors [16, pp. 1 – 49]. Processor frequencies well over 100 GHz – surpassing the semiconductor competition by more than two orders of magnitude – appear feasible. Special processors, especially for ultrafast digital signal processing, are of interest here. In this logic family, the bit is the presence of a switching pulse lasting a few picoseconds in a time window corresponding to a 2π phase change in the Josephson relation. Josephson junctions of the type illustrated in Figure 15 A are used. The functionality of the ultrafast RSFQ basic circuits has already been demonstrated with niobium. One sensational result is the demonstration that a 32-bit RSFQ shift register at 77 K can be operated at a frequency of over 100 GHz [19]. The experiment involved HT-superconductor nanobridges, which, however, exhibit an unacceptable error rate (one wrong bit every 10 min), but the convertibility

of RSFQ circuits to the still-unperfected HT superconducting technology has now been proved feasible (at least for fault-tolerant circuits).

The basis of the Josephson voltage standard is that a Josephson junction irradiated with high-frequency radiation (frequency f) exhibits current steps at multiples of the voltage $U = h/2\,ef$. Modern Josephson voltage standards for 1 – 10 V consist of thousands of hysteretic niobium – aluminum oxide – niobium Josephson junctions connected in series, which are integrated into a superconducting microstrip conductor in such a way that all junctions are excited at the same high frequency (ca. 70 GHz) [15, pp. 21 – 36]. It appears that a new design will make it possible to lower the operating frequency to ca. 12 GHz [20]. In this way, the costs of the HF system can be cut by about an order of magnitude, which is conducive to adoption in industry.

4.2.3. SQUIDs

Superconducting quantum interference devices (SQUIDs) are extremely sensitive detectors for magnetic flux and magnetic fields. The SQUID exploits two fundamental effects of superconductivity: the Josephson effect and the single-valuedness of the quantum phase in a superconducting ring. The SQUID converts magnetic flux to electrical voltage. At very low temperatures, the intrinsic lower limit of energy resolution of a SQUID per hertz of bandwidth is given by the quantum noise, $\hbar \approx 10^{-34}$ J/Hz, as has been confirmed in laboratory specimens. For practical devices with efficient flux coupling, good helium-cooled SQUIDs achieve energy resolutions of around 30 $\hbar$ and field resolutions of ca. 10^{-15} T/Hz$^{1/2}$ at frequencies down to < 1 Hz. This high sensitivity has made SQUIDs vital for many important experiments and makes possible the measurement of extremely weak biomagnetic signals from human organs, such as the heart and brain, in the range of $10^2 - 10^5$ f T/Hz$^{1/2}$ (corresponding to 10^{-8} to 10^{-5} times the Earth's magnetic field). Measurement of biomagnetism can be regarded as the pioneering application of superconductivity in normal technology outside the physics laboratory.

The principles and technical design of SQUIDs have been presented in detail in textbooks and survey articles [21]. Here it is sufficient to illustrate the two most important versions (Fig. 16 A and B), the d.c. SQUID and the RF SQUID. Each utilizes Josephson junctions with hysteresis-free $I\,(U)$ characteristics, corresponding to Figure 15 A with parallel resistance R. In Figure 16 A, if magnetic flux Φ enters the superconducting ring (with inductance L_s) through the two identical Josephson junctions, the current – voltage characteristic of the ring will vary between two extreme positions (Fig. 16 C) corresponding to fluxes $n\Phi_0$ and $(n + 1/2)\Phi_0$, where $\Phi_0 = 2.0679 \times 10^{-15}$ Wb is the magnetic fluxoid quantum and n is an integer. If a fixed bias current $I_b > 2\,I_c$ is passed through the ring (where I_c is the critical current of the individual Josephson junction), the voltage drop U across the ring varies periodically in the flux with period Φ_0 (Fig. 16 E). The (a.c.) current – voltage characteristic of a resonant circuit made of an inductance L and a capac-

Figure 16. The two most important SQUID configurations
A) d.c. SQUID; B) RF SQUID; C), D) Extreme positions of the I versus U curve on variation of the magnetic flux; E) At a current operating point I_B, the voltage varies with period Φ_0

itance C, which is inductively coupled to a superconducting ring with a single Josephson junction, similarly varies with resonance frequency ω_T between two extreme positions, again corresponding to flux values of $n\Phi_0$ and $(n+1/2)\Phi_0$ in the ring (Fig. 16 D). If the amplitude of the high-frequency current is set equal to a current step of the I_{rf} versus U_{rf} curve and the flux Φ in the ring is varied, then U_{rf} also varies periodically with period Φ_0.

The readout electronics of a sensitive SQUID magnetometer operates as a null detector by strong reverse feedback with the aid of a compensating coil, which compensates a change in external flux Φ with a flux resolution down to ca. $10^{-6}\,\Phi_0/\mathrm{Hz}^{1/2}$. Important factors in the optimal functioning of a SQUID with characteristics 16 C and 16 D are the selection of parameters such that $2L_sI_c \approx \Phi_0$ (quantization condition) and $I_c \sim k_BT/\Phi_0$ is large enough that thermal flux noise at the SQUID operating temperature is not by itself of the order of $\Phi_0/2$ (maximum driving of SQUID). This constraint limits SQUID inductances to less than ca. 10^{-9} H at 4 K, and less than ca. 10^{-10} H at 77 K. As a result, stringent standards apply to the microfabrication of HT-superconductor SQUIDs to concentrate magnetic flux in appropriately small SQUID rings a few micrometers in diameter. The flux concentration is achieved by means of flux transformers (see Section 4.1.1), which are fabricated as thin-film structures (Fig. 17 A).

Flux concentrators without thin-film coils, in the form of slotted single-layer film structures, are less effective as transformers but are easier to manufacture.

Given the great sensitivity of SQUIDs, interference suppression is a key problem. The first thing is to maintain the functioning of the SQUID that is experiencing interference, then to isolate the signal for measurement from the noise. In the presence of external fields that vary only slightly with position, very small local field gradients can be isolated and measured if the pickup coil is made in the form of a gradiometer of first or higher order (Fig. 17 A – C). Strong interference fields are generally compensated with passive and active shielding (magnetically shielded compartments, large coils). The more open the system, the sooner it will run into dynamic limiting. If this limiting is not overcome, electronic and "software" gradiometers may be used. In these approaches, magnetometer signals are corrected in either analog or digital mode. The problem of suppressing interference is identical for SQUIDs based on low- and high-temperature superconductors. The problem with LT-superconductor SQUIDs is not so much their field sensitivity ($\approx$1 f T/Hz$^{1/2}$ at $\geq$ 1 Hz) as the performance and the cost/benefit ratio of the system. A SQUID magnetometer optimized in this respect is shown in Figure 18 [22]. This repre-

sents the state of the art for LT SQUIDs in large shielded systems.

4.2.4. SQUIDs and Biomagnetism

Figure 19 shows the amplitudes and frequencies of magnetic fields produced by physiological currents in some human organs. If the smallest biomagnetic signals of interest are to be resolved, the field noise contribution B_N of the SQUID should be no greater than a few tens of $fT/Hz^{1/2}$ in the frequency range from ca. 0.3 Hz to ca. 300 Hz. Also shown in Figure 19 are the interference fields in a typical urban environment, and geomagnetic activity. Measurement of biomagnetic signals, particularly from the heart and brain, is possible only if the interference fields are suppressed by several orders of magnitude. The advantage of the magnetocardiogram (MCG) and magnetoencephalogram (MEG) over ECG and EEG lies in the formation of large, parallel multichannel arrays with noninvasive localization and spatial and temporal resolution of spontaneous biological electrical current distributions. Not until the mid-1980s did reliable multichannel SQUID arrays become possible, based on Josephson junctions and niobium thin-film technology. Finally, in 1989–1991, the first commercial systems with more than 30 channels became available. These were large enough to permit spatiotemporally localized recording of biological currents in the heart or brain with a fixed array. Field resolution in each channel is 5–20 $fT/Hz^{1/2}$ for frequencies larger than 0.5 Hz. The first 37-channel system, the KRENIKON, was manufactured by Siemens [23]. Commercial systems now have up to 64 channels [24], and systems with up to 122 channels are being developed.

What the physician obtains is a series of three-dimensional images of the organism, derived from magnetic-resonance or X-ray computer tomography, onto which the space and time distributions of current are projected. Approximately ten such systems are in use worldwide. The clinical relevance of the method has been demonstrated particularly in the noninvasive localization of focal epilepsy combined with noninvasive radiotherapy (focused gamma-ray bundles), and noninvasive process monitoring (with SQUIDs) [25]. The method has also proven advantageous in the diagnosis of the heart condition Wolff–Parkinson–White syndrome. Applications in which biomagnetic measurements will probably be useful include Alzheimer's disease, schizophrenia, monitoring of recovery after trauma, and quantitative assessment of drug effects on brain function.

Figure 19. Frequency spectrum of biomagnetic signals compared with interference (noise) fields in an urban environment

The costs of such an apparatus – including the cooling system, magnetic shielding, interpretation system, and patient environment – are still very high (ca. € 2×10^6). This does not favor application of the device in a field important from the standpoint of patient numbers: noninvasive diagnosis of irregularities in cardiac rhythm. Nor is it contributing to the widespread adoption of this diagnostic technique. As a result, less costly methods of suppressing the interference fields are being sought, and attempts are being made to change over to the more easily cooled high-temperature superconductors.

4.3. Applications of HT Superconductors

It is now certain that the high-temperature superconductors, which have critical temperatures T_c above the temperature of liquid nitrogen (T = 77 K or − 196 °C) will find practical applications. They are already used in microelec-

tronics, where the currents and magnetic fields required are much lower than in power engineering and magnets. Power applications require conductors and cables of considerable size. HT-superconductor wires fabricated by ceramic techniques fall far short of the current-carrying capacity (at 77 K) needed in the magnetic fields encountered in industry, although advances have been made.

In contrast, microelectronic circuits can be fabricated by thin-film methods such as those known from the semiconductor industry. Superconducting properties relevant to applications, such as critical current density J_c and microwave losses (defined by the surface resistance R_s), have practically been optimized in epitaxial thin-film HT-superconductor structures. For certain components and circuit types, these properties offer marked technical advantages over established technical solutions based on normal metals at room temperature or with cooling.

4.3.1. Materials and Techniques for HT-Superconducting Electronics

The classes of HT-superconducting materials significant for microelectronic applications at 77 K are listed in Table 3 (Section 3.3). Most of the experience accumulated up to now is with YBCO. Because of the strong crystalline and electronic anisotropy of all cuprates, as well as the extremely short interaction length (coherence length) of the superconducting charge carriers, this material must be used in the form of oriented, virtually single-crystal epitaxial films which are practically free of grain boundaries. The quality attribute of such films is a critical current density $J_c > 5\times10^6$ A/cm^2 at 77 K in their own field together with the highest possible HF limiting field strength H_{rf} (the value above which high-frequency losses in the material increase rapidly). Until quite recently, films of such high quality could be made only from YBCO or other members of the REBCO (RE = rare earth) class; the best quality at present is $J_c = 5\times10^7$ A/cm^2 (50–60 K, 0 T) and $H_{rf} = 40$ kA/m (4 K) [26]. Methods have been devised for fabricating epitaxial REBCO films (*c*-axis perpendicular to film plane) on oxide substrates such as MgO, ZrO_2, $SrTiO_3$, $LaAlO_3$, and $NdGaO_3$. Substrate wafers four inches in diameter can now be obtained. Heteroepitaxial multilayer structures of YBCO and semiconducting (PrBCO) or insulating perovskites ($SrTiO_3$, $LaAlO_3$) have also been made. Accordingly, YBCO is preferred for most microelectronic application studies. High-quality TBCCO films, of interest due to the higher T_c, have also been used in high-frequency devices, but no multilayer coating technique is in prospect for this material, and the small H_{rf} (around 800 A/m) means that only small-signal applications are possible; hence it is not clear whether TBCCO will compete with YBCO. Advances have been made in the fabrication of BSCCO films and devices (single-layer films only), but film production has proved much more difficult than for YBCO.

Targets in material development are higher crystalline quality of HT-superconductor films, over larger areas, on substrates with low losses in the microwave band, at the highest possible HF field strengths, and the extremely difficult integration of HT superconductors with semiconductors such as Si and GaAs. Progress on the last problem is relatively slow, but integrated superconductor – semiconductor electronics have great potential. Buffer films are now available for YBCO on Si and GaAs, permitting deposition of high-quality YBCO films on 4″ substrates [27].

The development of processing techniques is marked by (1) major advances in the use of CVD for large-area film deposition; (2) marked reduction of the defect concentration in epitaxial films; (3) heteroepitaxy of HT superconductors and oxide-type dielectrics on prestructured surfaces and over steps (thin-film wiring, high-frequency components) and on edges (edge-type Josephson junctions); (4) epitaxy of *a*-axis films and heteroepitaxy with semiconducting perovskites yielding planar Josephson junctions; (5) epitaxy of buffer layers [e.g., ZrO_2 as Yttria stabilized ZrO_2 (YSZ)] under YBCO on "standard" large-area substrates such as 4″ sapphire wafers; and (6) the replacement of wet-etching processes (H_3PO_4 or ethylenediaminetetraacetic acid) by micromechanical process masks and by liftoff and dry-etching processes. However, in the absence of suitable selective reactive ion-etching processes, ion-beam methods must be employed.

4.3.2. Operating Temperatures of HT-Superconducting Electronics

The main applications of superconducting electronics occur where the cost of cooling is not a serious economic or technical problem. The temperature of cheap liquid nitrogen (77 K) – roughly the highest temperature at which HT-superconducting electronics can be expected to operate – is in contrast to electronics based on low-temperature (LT) superconductors, which are limited to temperatures around 4 K. Simple one-stage refrigerators can operate economically and reliably above 40 – 45 K, so that practical operating temperatures for HT-superconducting electronics are between 45 and 77 K. Thus the technical, economic, and psychological obstacle of helium cooling, which has hindered broader acceptance of LT-superconducting cryoelectronics, can be dispensed with.

4.3.3. Passive Components Based on HT Superconductors

A series of prototype high-quality (Q) coplanar, microstrip, and strip-line resonators have been made with YBCO films [28, 29]. Typical Q values may be several orders of magnitude higher than those of equivalent components made with cooled normal metal. Narrow-band multipole filters with very low insertion loss can be devised by combining a series of planar resonators. For example, a four-pole microstrip filter for the X band is made with YBCO and operates at 77 K. It has a 3 dB bandwidth of about 500 MHz (2 %), over 55 dB out-of-band suppression, dynamic range of over 20 dBm (100 mW), and maximum insertion loss under 2 dB [30].

The quality gains with YBCO films and new filter designs should increase the high-frequency rating to input power levels ≥ 50 W [26], so that usable HT-superconducting filters are possible on the transmitter end. Their compactness might make such filters useful in satellite communications and radar. Because high-frequency losses are low, planar microwave antennas can be miniaturized to dimensions much smaller than half the vacuum wavelength, while maintaining an adequate efficiency, so that the antennas can be made to operate over a wide band by appropriate folding. For the HTSSE II space experiment, the University of Wuppertal has devised a multielement antenna with radiated frequencies of 4.5 and 9.5 GHz in different directions [31]. The propagation of electrical pulses in the THz band with low dispersion and low losses has been demonstrated with YBCO strip lines [32]. Simple examples of wide-band delay lines have been realized with YBCO films of low to moderate quality [33]. The calculated and measured strip-line loss in dB/m are compared in Figure 14. For simple microstrip lines on $LaAlO_3$ wafers 50 mm in diameter, delays of 10 ns and a pass-band curve up to 20 GHz can be anticipated. A strip line 0.7 m long with modulated width, serving as a "chirp" filter, was fabricated on such a wafer; the bandwidth was 2.6 GHz, the center frequency 4 GHz, and the (dispersive) delay 8 ns, so that the time – bandwidth product was 21 [28]. Daimler-Benz has developed and reported a new approach to the implementation of such HT-superconductor chirp filters [33]. With a coplanar line configuration on a substrate measuring 3.8×3.8 inches, delays of over 100 ns were achieved for the first time. The (limited) advantages of HT superconductors as high-density conducting paths for chip-to-chip connections in computers (dispersionless, low-loss) are discussed in [34]. There is not as yet any prospect that the prerequisites for such paths, in particular the multilayer integration of HT superconductors and dielectrics with through-contacts and bump contacts.

Progress on passive HT-superconductor components in 1992 – 1993 suggests several future trends in development: low insertion losses at 77 K for a number of narrow- and wide-band components; marked extension of applications to analog signal processing, initially in satellite communications, radar, and other microwave hardware ranging down to the K band. Passive superconducting components may come into use in high-frequency technology, but only in the form of HT-superconductor components. Furthermore, a wide variety of such components must be integrated into superconductor- and/or semiconductor-based systems and subsystems, in particular so that the expense of cooling on board a satellite can be justified.

4.3.4. HT-Superconductor Radiation Detectors

Highly sensitive HT-superconductor bolometers for measuring thermal radiation can be created simply by operating a superconducting strip in the temperature range containing the very steep $R(T)$ transition to normal conduction, then measuring the voltage drop across the strip, which varies as a function of the incident radiation. Above 77 K, infrared sensitivity close to the theoretical limit of $D* = 2 \times 10^{10}$ cm Hz$^{1/2}$ W^{-1} can be achieved. Suitable design will allow response times in the microsecond range and shorter.

Prototypes of bolometers for infrared and far infrared, which can be used in spectrometry, radio astronomy, and space applications, have been described [28]. One such detector is also intended for deployment in the HTSSE experiment. The state of the art is as follows: sensitivity up to 1750 V/W, noise down to 7 ± 10^{-10} W/Hz$^{1/2}$ at 10 Hz, signal risetimes < 0.5 ms, chopper modulation at 100 Hz for 45 nm thick YBCO on a thinned Si substrate with buffer [35]. The feasibility of much faster IR quantum detectors is still being investigated, but no trend in development can yet be discerned.

4.3.5. Nonlinear HT-Superconductor Components

Figure 20 summarizes the types of Josephson junctions based on high-temperature superconductors. Up until 1990, only the "weak-link" junctions (Figs. 15 A and 20 A), formed at natural grain boundaries in polycrystalline ceramics or films, exhibited the Josephson effect at 77 K. The use of these devices for SQUIDs, microwave detectors, and mixers was demonstrated between 1987 and 1989. However, their uncontrollable characteristics made them unsuitable as a basis for an IC technology involving HT superconductors. The situation changed in 1990 when the first thin-film Josephson junctions made by a controlled process from epitaxial YBCO films and having usable weak-link $I-U$ characteristics at temperatures up to 77 K appeared [28, 29]. These Josephson junctions utilized a weak-link coupling at artificial grain boundaries [36–38] (Fig. 20 B), in YBCO – PrBCO – YBCO heterostructures [39] (Fig. 20 D), or in YBCO – Ag – YBCO junctions [40] (Fig. 20 E, produced in situ as a step junction). The use of epitaxial films also led to a reduction of the low-frequency $1/f$ noise, which originates chiefly at grain boundaries. A major improvement has been the reduction in interfacial resistance between the superconductor and the barrier material, which can be achieved by in-situ processes [41] or by wet etching [42]. Edge junctions (Fig. 20 D) with $CaRuO_3$ as the epitaxially-grown normally conducting barrier material, are now favored for future digital circuits because of the good reproducibility of I_c and R_N [43]. Microbridges etched by electron beams (Fig. 20 G)

Figure 20. Types of Josephson junctions made with high-temperature superconductors [7, p. 434]
A) Grain-boundary junction (polycrystalline film); B) Grain-boundary junction (bicrystalline substrate or bicrystalline buffer); C) Step-edge junction (two different junctions connected in series); D) Edge junction with epitaxial barrier; E) Normally conducting bridge as in situ step junction; F) Planar junctions [not for 77 K operation (ca. 1990)]; G) Weakened bridge

exhibit excellent Josephson qualities but lack adequate stability [44]. Planar Josephson junctions (Fig. 20 F) for service at 77 K are currently not in prospect.

In contrast to low-temperature superconductor technology, it is still an open question whether HT-superconductor tunnel-type Josephson junctions (Fig. 15 B) are feasible for fast switches.

4.3.6. HT-Superconductor SQUIDs

Shortly after the discovery of high-temperature superconductivity in cuprates, three more discoveries came in quick succession: the Josephson effect, the SQUID function, and the fact that these effects occurred even above 77 K. However, extensive experimental activity soon showed that the sensitivity of HT SQUIDs was limited not only by thermal noise ($\sim k_B T$), but even more severely by a high level of low-frequency $1/f$ type noise. Moreover, the flux transfer from a pickup area to the SQUID, known for LT superconductors (flux transformer, usually made from niobium wire), has not been accomplished for HT superconductors using HTS wire. Such wire is still not available with the required noise performance. The outlook for HT SQUIDs was thus limited to applications where very high energy and field sensitivities were not required. SQUIDs based on HT superconductors can be used to advantage in nondestructive quality control in cases where classical flux-gate methods are insufficiently sensitive.

Improvements in the sensitivity of high-temperature SQUIDs are directly linked with reductions in $1/f$ noise and improved flux coupling. Until about 1989 – 1990, natural grain boundaries in massive ceramic HT superconductors or polycrystalline thin-film HT superconductors, chiefly of YBCO, served as Josephson junctions. The result was a large contribution to low-frequency flux noise from the many grains in the polycrystalline superconducting material. Individual grain boundaries serving as Josephson junctions in a thallium cuprate film, which is otherwise virtually free of grain boundaries, exhibited the lowest level of $1/f$ noise [45]. Since ca. 1990, alternative methods have been devised for making Josephson junctions at specified positions in the circuit. A successful method is the production of grain boundaries at specified points in epitaxial YBCO films (Fig. 20 B and C), which are otherwise of practically single-crystal character and thus low in noise, or to make the junction with a normally conducting bridge (Fig. 20 E).

Using step-edge junctions (Fig. 20 C) [38] and a SQUID inductance of 20 pH, the Siemens group obtained a SQUID energy resolution of 6×10^{-31} J/Hz (roughly $1000\,h$) above 10 Hz at 77 K [46,47]. The BTI group used highly reproducible superconductor/normal conductor/superconductor Josephson junctions, achieving 9×10^{-30} J/Hz above 1 Hz [40]. The resolution reached 3×10^{-31} J/Hz when submicrometer grain-boundary junctions were employed, but only at frequencies above 60 kHz, which is outside the range encountered in biomagnetic applications [48]. These best energy-resolution figures for HT d.c. SQUIDs thus correspond to the 10^{-30} J/Hz resolution of commercial helium-cooled d.c. SQUIDs, but are an order of magnitude lower than that of the d.c. SQUIDs in multichannel systems using LT superconductors. The HT SQUIDs under discussion did not, however, have flux coupling and so were not field-sensitive.

As a first step toward effective flux coupling in HT SQUIDs, planar high-temperature thin-film flux transformers were fabricated and combined with HT d.c. SQUIDs by the flip-chip technique, in which two chips are cemented with their active surfaces together. Such a flux transformer, with a magnetometer coupling loop combined with a grain-boundary d.c. SQUID, was first used by CONDUCTUS in the United States to record magnetic cardiac signals inside a magnetic shield; the field resolution was 600 f T/Hz$^{1/2}$ at 77 K above 10 Hz [49]. This concept was employed recently by the Sensor-Lab group in Japan, which implemented a functional SQUID array and recorded magnetocardiograms on 16 parallel channels with a field sensitivity of 370 f T/Hz$^{1/2}$ [50].

Another approach was taken by a team at the Jülich Nuclear Research Center, which created a single structure by combining HT RF SQUIDs operating at 77 K with grain-boundary Josephson junctions and large thin-film flux concentrators. The operating frequency was increased from the usual 20 – 150 MHz. In magnetic shielding, a field sensitivity of 170 f T/Hz$^{1/2}$

was achieved above 1 Hz in this way. With the addition of a ceramic flux concentrator 4.3 cm in diameter, the field sensitivity was boosted to 60 f T/Hz$^{1/2}$ above 5 Hz. The energy resolution of ca. 5×10^{-29} J/Hz was as good as that of helium-cooled RF SQUIDs. The system was able to record not only MCG cardiac signals (time signal) deemed diagnostically usable by a medical research group, but also registered signals of the human brain in the MEG for the first time [51]. Also a first-order electronic gradiometer of HT-superconductor type having field noise under 300 f T/Hz$^{1/2}$ was operated successfully above 2 Hz without magnetic shielding [52]. To derive medically relevant information from such data, however, and to perform measurements in clinics with their substantially higher ambient noise level, extensive work on noise suppression is still needed.

Figure 21. YBCO conducting-path layout of a direct-coupled d.c. SQUID, designed at University of California, Berkeley [49]

Progress in 1993 has created the prospect of a field sensitivity in the clinically relevant range of 20 f T/Hz$^{1/2}$. With a direct-coupled d.c. SQUID (Fig. 21), in which a magnetometer ring couples its signal into the SQUID ring via a conducting path, the Berkeley group increased the sensitivity to 39 f T/Hz$^{1/2}$ at 1 Hz [53]. This SQUID with integrated magnetometer consists of one thin-film layer. Advances in multilayer technology suggest that SQUID sensitivity can be boosted by at least a factor of two with flux transformers (which are necessarily two-layer devices). Using the flip-chip technique, the Siemens group has now achieved 65 f T/Hz$^{1/2}$ at 77 K and 5 Hz, using a thin-film flux transformer, a magnetometer with 0.4 cm^2 area, and a high-temperature d.c. SQUID. In a few optimal cases, itwas found that the flux transformer does not contribute to the noise [54].

4.4. Refrigerators for Cryoelectronics

The availability of reliable, long-lived, low-vibration, compact, economical refrigerators offering capacities of ca. 1 W at 80 K is very important for the wider adoption of cryoelectronics in industry. Although liquid nitrogen is easy to handle, there are advantages to a closed cooling cycle. Major progress has been made in Stirling and pulse-tube coolers. A Stirling cooler made by TRW offers cooling power of 250 mW at 65 K; the cooler weighs 1.4 kg, and the electronics 0.75 kg. The compressor consumes 12 W, and the electronics 5 W, part of which is used to suppress vibration. The lifetime is claimed to be 10 years. Given reasonable sales figures, prices should be in the range of \$ 10 000 – 20 000 in 1993 [55]. Pulse-tube coolers have the further advantage that there are no moving parts in the vicinity of the cooler, and the compressor can be located many meters away. Toshiba, Nihon University, and the Institute of Space and Astronautical Science [56] have developed a cooler with a 278 W linear drive, providing 10 W of cooling power at 80 K and a minimum temperature of 35 K.

The simplified cooling that can be employed with high-temperature superconductors, coupled with substantial progress in cryoelectronic HT-superconductor devices, leading to performance figures similar to those achieved with low-temperature superconductors, have extended the range of electronic applications of superconductivity to include nonlaboratory settings.

5. Application of Superconductivity in Magnet and Power Engineering

5.1. Introduction

The potential uses of superconductivity in magnet technology and power engineering can be divided into two broad categories:

1) In electrical equipment of conventional design (generators, motors, transformers, cables, etc.), the use of superconductors leads to a marked reduction in size and weight and to an appreciable gain in efficiency (energy savings).
2) The introduction of superconductors makes it possible to devise new components that may play a key role in future energy generation and distribution systems, including fusion reactors with magnetic plasma confinement, magnetohydrodynamic energy conversion, superconducting magnetic energy storage (SMES), and superconducting current limiters. On the basis of conventional technonolgy, these devices can either not be realized at all, or not at acceptable costs. The same holds for magnets with flux densities > 0.5 T for medical magnetic resonance imaging (MRI).

In the first category, the economic competitiveness of superconducting technology plays an important role. For many applications of metallic superconductors, the economic breakeven point in relation to present-day technology comes at very high unit capacities, where there may not yet be any demand. The economic difficulty results in part from expensive, inefficient cooling with liquid helium at 4.2 K (efficiency $\leq 0.4\,\%$). Technical-economic studies have shown that smaller unit capacities can become economically competitive with the new oxide-ceramic high-temperature superconductors and the far simpler and more efficient liquid-nitrogen cooling at 77 K (efficiency $\approx 10\,\%$). The use of the new superconducting technology, however, presupposes critical current densities $\geq 10^5$ A/cm^2 at 5 T and conductor prices close to those of metallic superconductors (e.g., € 5 km^{-1} A^{-1} for NbTi).

Superconductivity is essential for the second category of applications. It can be implemented with metallic superconductors, but the use of oxide-ceramic superconductors may yield a further gain in efficiency and decrease operating costs.

5.2. Industrial Superconductors

5.2.1. Metallic Superconductors

By virtue of its upper critical magnetic flux density H_{c2} (Table 2), NbTi at 4.2 K is used in magnetic fields up to 10 T, and at 1.8 K (superfluid He), up to 12 T. The predominant superconductor for the range of 12 – 20 T is Nb_3Sn. Figure 5 shows how the critical current densities of these materials depend on the magnetic field. Other candidates for use in high fields are Nb_3Al and V_3Ga.

In general, metallic superconductors are fabricated by co-extrusion (extrusion, drawing, rolling) in the shape of multifilament or multicore conductors containing a great number (up to tens of thousands) of thin superconducting filaments embedded in a matrix of normally conducting material. NbTi conductors for d.c. applications are made with a matrix of high-conductivity copper (Fig. 22 A), which can be processed directly with the ductile NbTi. In the case of the more brittle Nb_3Sn, a complicated fabrication method (bronze technique) leads to Nb_3Sn filaments in a high-resistance matrix of CuSn [57]. For d.c. applications, this is combined with a core or jacket of high-conductivity Cu, isolated from the CuSn by a tantalum diffusion barrier (Fig. 22 B). In both cases, the high-conductivity copper stabilizes the conductors in case of malfunctions (e.g., a sudden transition to the normally conducting state, known as quenching), by acting as a short-term current and heat bypass. The ratio of superconductor to stabilizing metal can vary between 1:1 and 1:20, depending on the application.

The diameters of the superconductor filaments lie in the range of 1 – 50 µm for d.c. applications. The small diameters are required to confer stability against changes in the magnetic flux, which might initiate normal conduction. The criterion for adiabatic stability is given approximately by [58]:

$$J_c\, D_{SC} < \sqrt{\gamma\, c_v\,(T)\,(T_c - T_0)\,/\mu_0} \qquad (5)$$

where J_c is the critical current density of the superconductor, D_{SC} the thickness of the super-

conductor, γ the mass density, $c_v(T)$ the specific heat, T_c the critical temperature of the superconductor, T_0 the operating temperature, and $\mu_0 = 4\pi \times 10^{-7}$ H/m the permeability of free space.

With regard to time-variant magnetic fields, the filaments must be electrically decoupled from one another, which is achieved by twisting the conductors. For power applications, conductors rated at between 100 A and 100 kA are required. These capacities are attained by fabricating several conductors (Fig. 22) into transposed stranded wires or Roebel bars; the individual conductors must be electrically decoupled for a.c. applications. Figure 23 shows a Roebel bar used for the field winding of a 400 MVA test generator in development [59].

If metallic multifilament superconductors are subjected to periodically varying (a.c.) fields at line frequency (50 or 60 Hz) and significant amplitude (e.g., in generators, transformers, and motors), the filament diameters must be lowered to ca. 0.1 µm to minimize hysteresis losses. The hysteresis loss per unit volume is proportional to the filament diameter [60]:

$$P_H = 1/2 f D_{SC} \Delta B J_c V_{SC} \quad (6)$$

Figure 22. Metallic multifilament superconductors
A) 27 594 NbTi filaments, diameter 5 µm, in Cu matrix; B) 23 000 Nb_3Sn filaments, diameter 4 µm, in CuSn matrix
The filaments are assembled into bundles (source: Vacuumschmelze Hanau)

Figure 23. Transposed high-current conductor (Roebel bar) made of NbTi multifilament conductors
Current 10 k at 5 T (source: Vacuumschmelze Hanau)

where f is the frequency, D_{SC} the diameter of the superconducting filaments, ΔB is the field amplitude ($= 2\sqrt{2} \times B_{eff}$, perpendicular to filament thickness), J_c is the critical current density, and V_{SC} is the volume of the superconductor.

At lower field amplitudes, such as those in high-power transmission cables, the hysteresis losses are independent of superconductor thicknesses:

$$P_H = 2/3\mu_0^2 f \Delta B^3 A_{SC}/J_c \quad (7)$$

where A_{SC} is the area of the superconductor exposed to the field.

To minimize coupling losses (eddy-current losses) in the metal matrix, high-resistance alloys such as CuNi are employed.

5.2.2. Oxide-Ceramic Superconductors

For magnet and power applications with liquid-nitrogen cooling (77 K), the principal compounds of interest are $YBa_2Cu_3O_7$ and the lead-doped bismuth compound $(BiPb)_2Sr_2Ca_2Cu_3O_{10}$ (Bi-2223, see Section 3.3), with a high degree of texture. The state of the art is less advanced than in metallic superconductors, particularly as to the critical current density at 77 K and the control of the fabrication process for long conductor lengths. However, major progress has already been made.

The powder in silver tube process [61] is employed to make wires and thin tapes of Bi-2223 in lengths of up to 1000 m. Critical current densities are 10^4 A/cm^2 in zero magnetic field. Current densities of ca. 7×10^4 A/cm^2 have been achieved in short laboratory samples. Because its critical current density at 77 K is highly sensitive to magnetic fields, Bi-2223 at 77 K appears suitable only for low-field applications such as cables, current limiters, and possibly transformers.

The preferred configuration is also the multifilament conductor (Fig. 24). Such conductors can be stretched up to 0.3 % without degradation of the critical current density. The filament diameter can be made at least an order of magnitude larger than with metallic superconductors, chiefly because of the higher heat capacity at 77 K (adiabatic stability, see Eq. 5), and, in view of hysteresis losses at 50 – 60 Hz, the higher efficiency of liquid nitrogen cooling systems.

Figure 24. High-temperature multifilament superconducting wire made of Ag matrix with 37 filaments ca. 100 µm in diameter (source: Vacuumschmelze Hanau)

Two approaches have been taken in the development of highly textured conductors of $YBa_2Cu_3O_7$, which appears better suited than Bi-2223 for applications involving moderate and strong magnetic fields. The first is melt-texturing growth (MTG, see Section 3.3), while the second involves thin-film techniques, laser ablation, and chemical vapor deposition (CVD) for the production of thick layers deposited on metal tapes (Hastelloy) with intermediate buffer films (ZrO_2). The MTG process is particularly suitable for the fabrication of massive superconducting parts such as those used in passive magnetic bearings, superconducting permanent magnets, or magnetic shieldings. Critical current densities J_c at 77 K of 4×10^4 A/cm^2 have been attained in magnetic fields of 1.5 T [62]. The other approach has so far led to laboratory specimens with YBCO a few µm thick and having the following critical current densities at 77 K: 6×10^5 A/cm^2 (zero field), 8×10^4 A/cm^2 (0.4 T) [63].

5.3. Potential Superconductivity for Improvements in Conventional Electrical Devices

5.3.1. Superconducting Magnets for High-Energy Physics

High-energy physics is one of the most important applications for magnets made of metallic superconductors. Many gigantic d.c. magnets have been built for elementary particle detectors

as well as beam-guidance magnets outside the accelerator ring, and have been operated without problems for years in many laboratories worldwide. These magnets have yielded appreciable savings in electrical energy consumption and operating costs. Their higher magnetic flux densities (a factor of two to five greater than conventional iron-core magnets) permit substantial reductions in size.

These advantages have led to all modern ring-type particle accelerators being built with superconducting magnets. Examples are the 1000 GeV proton accelerator rings (Tevatron) at Fermilab in the United States (in service since 1984) and the Hera accelerator at DESY, Hamburg (operating since 1991), which have ca. 1000 and 630 dipole and quadrupole magnets, respectively, installed in their 6 km circumference rings. Larger machines of the same type are in the early phase of construction (the Superconducting Supercollider, SSC, with an 83 km ring) or in the planning stage (CERN's Large Hadron Collider, LHC, at Geneva, with a 27 km ring).

Replacing metallic superconductors with HT superconductors has little effect on installation costs, but the electrical energy costs for running these accelerators can be lowered approximately by a factor of four.

5.3.2. Magnetic Separation and Purification

In a magnetic separation process, ferromagnetic or paramagnetic particles are extracted from a stream of nonmagnetic material by the action of magnetic forces. The force acting on the magnetic particles is given by

$$F \sim \chi V \mu_0 H \nabla H \tag{8}$$

where χ is the susceptibility of the particles, V the particle volume, H the magnetizing field, and ∇H is the field gradient acting on the particle.

The use of superconducting magnets makes it possible, above all, to greatly increase the magnetic field strength and the field gradient over the values in conventional magnetic separators ($\mu_0 H \leq 1$ T). This allows magnetic separation of even weakly ferromagnetic or paramagnetic particles of small size, for which expensive and environmentally unfriendly chemical flotation methods were formerly required. Other potential applications of separators with superconducting magnets are the removal of magnetic impurities from minerals, water treatment, desulfurization, recovery of radioactive materials, and many other chemical and biological processes. This type of separator has the further advantage of a low energy consumption, roughly an order of magnitude less than for equal-capacity systems using water-cooled windings.

In the past, a number of pilot plants with liquid-helium-cooled NbTi windings were tested with success [64]. A favored separator type is the high-gradient magnetic separator (HGMS) illustrated in Figure 25. The magnetic field is generated by a superconducting solenoid; the field gradient is established by a stack of fine magnetic steel meshes (matrix) in which the magnetic particles are trapped while nonmagnetic particles can pass without hindrance. The magnetic field is then turned off, and the magnetic material is washed out with water, after which the process begins anew.

Figure 25. Schematic diagram of a high-gradient magnetic separator (HGMS)
a) Magnetic steel matrix; b) Superconducting magnetic field coil

The use of high-temperature superconductors, so that cheaper and more robust liquid nitrogen cooling can be employed, will greatly improve the market prospects for superconducting magnetic separators.

5.3.3. Superconducting Levitation for High-Speed Transportation Systems

Electromagnetic suspension, guidance, and propulsion systems are under consideration for a high-speed surface transportation system with speeds of 500 km/h or more.

In the electrodynamic system, short-circuited superconducting coils carrying a persistent current are mounted on either side of the chassis of the passenger vehicle (Fig. 26). Stationary, room-temperature copper suspension and guidance coils are located on either side of the roadway; when the vehicle moves relative to these, the magnetic flux of the superconducting coils (ca. 3 T) induces currents in the stationary coils, which exert a repulsive electromagnetic force that stably supports and guides the vehicle. An ironless linear synchronous motor with active roadway provides the propulsive force. Stationary copper drive coils embedded in the roadway are sectionally fed with a variable-frequency three-phase current to produce a traveling electromagnetic wave; the interaction of this wave with the d.c. flux of the superconducting magnets in the vehicle generates the propelling force. This system has the following advantages:

1) Wide air gap ($\geq$100 mm) for suspension, guidance, and propulsion
2) No need for air-gap regulation
3) Problem-free transmission of high power to the high-speed vehicle through contactless propulsion
4) No need for magnet power supply on board the vehicle

The performance of the system has been demonstrated in large test facilities in Europe and Japan [65, 66]. In the latter case, a 7 km test track carried a 10 t experimental vehicle at speeds up to 517 km/h as early as 1979. With the more realistic MLU 002 experimental vehicle (weight 17 t, length 22 m, capacity 44 passengers), speeds of around 400 km/h were attained on the same test track in 1989. The final introduction of the system into public transport is planned to take place by 1997, with prototype cars running on a new test track, ca. 43 km long, west of Tokyo.

The superconducting magnets use NbTi, but subsequent changeover to HT superconductors is planned. However, this will have little effect on the economics of the system since superconductivity accounts for only 1 – 2 % of costs.

5.3.4. Generators and Motors with Superconducting Windings

The power of an electrical machine with a cylindrical air gap is described by the proportionality

$$P \sim A_{\mathrm{eff}}\, B_{\mathrm{r}}\, D^2\, Ln \tag{9}$$

where D is the diameter of the air gap between the rotor and stator windings, L the length of the active part of the machine, n the rotation speed of the rotor, A_{eff} the effective linear current density at the periphery of the air gap (stator winding), and B_{r} the radial magnetic flux density in the air gap.

Superconducting windings without magnetic iron give far higher magnetic flux densities than in conventional machines ($B_{\mathrm{r}} \approx 1$ T). Omitting the iron also makes it possible to increase the effective linear current density A_{eff}. As a result, superconducting machines can be built much smaller and lighter than conventional machines with the same power rating. The low electrical losses of superconducting windings (all losses in

Figure 27. Schematic diagram of rotor with superconducting field winding
a) Superconducting field winding; b) Torque tube extension; c) Torque tube; d) Warm damper shield; e) Thermal radiation shield; f) Vacuum; g) Helium transfer unit

d.c. windings are thermal) and the low rotor friction losses (reduced size) lead to marked gains in efficiency, especially for high-power machines.

Preferred types of machine are d.c. and synchronous devices, because superconducting d.c. windings (without hysteresis losses) can be used here. Efforts are being made worldwide to create large superconducting synchronous generators for use in power plants. The present design has only the rotating field winding made of superconducting material, with the stationary three-phase winding built of water-cooled stranded conductors that contain fine copper wires. In comparison with conventional generators, the volume and weight are reduced by about a factor of two for large machines (500 – 1000 MVA), and the efficiency is increased from 98.85 % to 99.5 %. The economic breakeven point for NbTi conductors is in the range of 600 – 800 MVA.

Figure 27 shows the concept for a rotor with a two-pole superconducting field winding, whose conductors are laid in the grooves of a nonmagnetic steel cylinder. The design features helium off-gas cooling for the ends of the torque-transmitting cylinder and a cold radiation shield; as a result, the cold field winding (at 4.2 K) experiences minimal thermal load. Warm and cold damping shields prevent undesirable interactions between the three-phase winding and the superconducting field winding during transient operating conditions such as short circuits. The helium transfer unit delivers liquid helium to the rotating field winding and extracts warm and cold helium gas from the rotor. An important project is the Japanese Super GM program, in which Japanese industry and utility companies are developing three rotors with various superconducting field windings for a model generator of the 70 MW class [67].

A field winding with high-temperature superconductors and liquid-nitrogen cooling will shift the economic breakeven point into the 200 – 400 MVA power range. Furthermore, a completely superconducting machine (with superconducting three-phase winding) would also be conceivable with HT superconductors.

In large d.c. machines, the use of superconducting windings is limited by problems in transmitting current from the stationary to the rotating parts (commutator in heteropolar machines, very high currents in homopolar machines).

5.3.5. Superconducting Transformers

Advances in low-loss a.c. superconductors with submicron filaments in a resistive CuNi matrix have increased interest in the superconducting transformer. Figure 28 shows schematically a superconducting transformer. For more efficient removal of hysteresis losses, the iron core is held

at room temperature, cooled with a liquid such as oil. The high-voltage and low-voltage windings are placed in a thermally insulated tank that surrounds the iron core; it is made of glass-fiber-reinforced plastic in order to block eddy-current losses. The wind-ings are cooled in a bath of liquid coolant, which is also to perform part of the function of the dielectric and so must be subcooled to prevent the formation of gas bubbles, which would result in undesirable partial discharges. Other vital components are the low-voltage and high-voltage bushings [68].

Figure 28. Schematic of a superconducting transformer (one phase)
a) Low-voltage connection; b) High-voltage connection; c) Oil tank; d) Iron yoke; e) Liquid coolant + electrical insulation; f) Coolant tank (glass-fiber-reinforced plastic); g) Thermal insulation; h) Oil; i) Superconducting low-voltage and high-voltage windings; j) Electrical insulation + coolant liquid; k) Iron core

Superconducting transformers offer the following advantages:

1) Marked reduction in 50 Hz winding losses, resulting in higher efficiency
2) Enhanced magnetic flux due to low winding losses, permitting a reduction in the cross section of flux-guiding iron and thus a substantial decrease in the weight and hysteresis losses of the iron core
3) Short-circuit current limiting through the transition of superconducting windings to the resistive normally conducting state, resulting in simpler mechanical design of the windings (milder forces) and thus leading to higher current densities and lighter-weight windings

In recent years, a number of small single-phase model transformers rated at 100 kVA have been built by using submicron NbTi filament conductors and have demonstrated the advantages of superconducting technology.

The benefits of superconductivity become much greater if the helium-cooled windings of metallic superconductors are replaced by liquid-nitrogen-cooled HT-superconductor windings. The following values have been obtained in a paper study for a 1000 MVA power transformer with windings made of a multicore HT-superconductor wire with 5 µm filaments (critical current density 10^5 A/cm^2) in a matrix of Ag – Al alloy (conventional figures in parentheses for comparison):

Weight of iron core	91 t (280 t)
Weight of windings	5 t (58 t)
Iron losses	100 kW (300 kW)
"Copper" losses (converted to 300 K)	200 kW (2000 kW)

5.3.6. Superconducting Power-Transmission Cables

High-power superconducting cables are of interest for underground power transmission in and near densely populated areas. Because transmission distances are relatively short (10 – 100 km), three-phase cable is preferred. Figure 29 (see next page) is a schematic of such a cable with HT-superconductor cores and liquid-nitrogen cooling. The flexible, hollow cable cores are of coaxial design. The actual phase conductors, made of superconductors (wires, tapes) in helical form, are enclosed in electrical insulation (wound tapes of polypropylene or polyethylene) and surrounded by a return conductor in which the a.c. current flows in the opposite direction to the phase conductors. As a result, no a.c. electromagnetic fields are produced outside the cores. A rigid or flexible double-walled thermal insulation layer surrounds the flexible cable cores; liquid coolant flows through the inner tube, while the outer one is at ambient temperature.

The practicability of superconducting cables has already been demonstrated in a number of experimental cables with helium-cooled metallic superconductors. The largest project was a

two-phase model cable of 115 m length with a power capacity of 1000 MVA at a voltage rating of 138 kV [69]. However, cables with helium cooling become economically competitive with conventional water-cooled oil cables only when carrying ca. 4000 MVA and up. Estimates indicate that the economic breakeven point for nitrogen-cooled HT-superconductor cables may be as low as 1000 MVA.

5.4. Novel Electrical Devices for Which Superconductors Are Indispensable

5.4.1. Magnets for Magnetic Resonance Imaging (MRI) and Spectroscopy

Two new medical diagnostic technologies are based on high-frequency signals emitted by protons or other nuclei (e.g., those of phosphorus or sodium) when they are aligned in a strong, highly homogeneous magnetic field and excited with high-frequency electromagnetic radiation. The detected signals are converted to cross-sectional images of the body, or used in local spectroscopy (chemical shift) to determine compounds important in metabolism.

Whole-body imaging employs magnetic fields ranging from 0.15 to ca. 1.5 T, while chemical shift spectroscopy uses fields of 1 – 2 T. Image quality improves with increasing magnetic flux density. For this reason, most installed MRI systems are equipped with superconducting magnets operating at flux densities between 0.5 and 2 T. The magnets are of cylindrical design (solenoids), 2 – 3 m long, with an internal bore about one meter in diameter in which the patient is placed (Fig. 30).

Figure 30. Superconducting magnet providing magnetic flux densities ≥ 0.5 T for magnetic resonance imaging (MRI)
a) Windings of Cu – NbTi multifilament conductors

The high spatial field homogeneity (better than ± 10 ppm in a sphere 0.5 m in diameter) required for these applications is achieved by using multicoil configurations and shim coils that surround the patient, like the high-frequency and gradient coil systems. The magnets exhibit high field stability over time ($\Delta B/B < 10^{-7}\ \mathrm{h}^{-1}$) due to the persistent-current operation that is possible with superconducting coils [70].

At present, all these superconducting magnets are constructed with NbTi metallic multicore conductors; ca. 1000 units are sold per year. A changeover to HT superconductors would lower capital costs by about 15 %, which corresponds to ca. 5 % for the entire system. In addition, cooling costs would be cut by \$ 100 000 to \$ 200 000 for a five-year service life.

5.4.2. Magnet Systems for Magnetic-Confinement Fusion Reactors

Magnetic plasma confinement is a promising route to the economical utilization of thermonuclear fusion energy. Two toroidal magnetic field configurations, the tokamak and the stellarator, appear especially suitable. Commercial reactors

Figure 31. Principal magnet configurations for magnetic-confinement fusion reactors
A) Tokamak; B) Stellarator

will require superconducting magnet systems to achieve the required power-plant efficiency.

The coil layouts of a tokamak and a stellarator are shown in Figure 31. In the axially-symmetrical tokamak configuration, the magnetic surfaces, which as surfaces of constant pressure contain the helical field lines, are established by superposing the toroidal main field and a poloidal magnetic field. The poloidal field is generated chiefly by an electric current induced in the toroidal plasma and also by annular internal transformer coils and external poloidal field coils. In the stellarator, the magnetic surfaces are generated solely by currents in external coils, so that a purely modular design is possible for the coil system. Magnetic flux densities of 5 – 6 T are required on the ring-shaped plasma axis in the tokamak configuration, corresponding to maximal magnetic fields of ca. 12 T at the superconducting coils, which can be attained only with Nb_3Sn conductors. The stellarator makes less stringent requirements on the magnetic field, which can be satisfied with NbTi conductors.

The technical feasibility of large magnets for fusion has been demonstrated in a number of large superconducting tokamak systems. Examples are the international LCT project at Oak Ridge National Laboratory in the United States, a toroidal configuration comprising six D-shaped magnets; and the TORE-SUPRA at the Centre d'Etudes Nucleaires Cadarache in France [71]. The largest international project at this time is the development of a magnet system

for the International Thermonuclear Experimental Reactor (ITER). This will be a tokamak-type system with D-shaped toroidal field coils measuring 18×11 m and poloidal field coils up to 25 m in diameter; the maximum flux density will be around 13 T. Other magnet configurations include the stellarator project (Wendelstein W7-X) at the Max Planck Institute for Plasma Physics, Garching, Germany; and the Large Helical Device (LHD) at the National Institute for Fusion Science (NIFS) in Japan.

The state of the art is based exclusively on metallic superconductors. There would be a variety of benefits in changing over to HT superconductors. First, the overall efficiency of a fusion power plant could be increased by 2 – 4 %. Simpler cooling would result in higher reliability and availability as well. However, this application would impose the most severe requirements (magnetic fields, forces) on the high-temperature superconductors.

5.4.3. Magnetohydrodynamic Energy Conversion

Magnetohydrodynamic (MHD) generators permit the direct conversion of thermal enthalpy to d.c. electricity. Strongly heated, ionized gas (natural gas) flows at high velocity perpendicular to an imposed magnetic field between electrodes on either side of the flow channel. If such a generator is installed as the first stage, upstream of a conventional steam-turbine loop, the overall efficiency of the combination power plant can be enhanced to ca. 50 %. For this, however, at least 20 % of the enthalpy must be extracted from the hot gas, which requires magnetic field strengths of at least 6 T. Due to these high values and the huge dimensions of actual commercial systems, dipole magnets 25 m long with a 5 m free bore are required. Therefore, only superconducting magnets can be considered (on reasons of efficiency). The properties of NbTi conductors are adequate.

Although a number of smaller model systems with superconducting magnets have been tested successfully, work ceased worldwide in the early 1980s due to aging problems with the channel wall and electrodes. In 1989, a new MHD program was begun in Italy [72].

Because the electrical energy consumed by superconducting magnets is only ca. 1 % of the energy generated, a changeover to HT superconductors would not result in any major savings in operating costs or gains in efficiency for an MHD system. The same applies to installation costs.

5.4.4. Superconducting Magnetic Energy Storage (SMES)

The ability of superconductors to carry direct current without losses means that a persistent current can be maintained in a short-circuited superconducting coil with no external current supply. This makes superconducting coils very attractive as a means of storing electrical energy directly, i.e., without conversion to other forms of energy. The stored energy is proportional to the square of the magnetic flux density and to the volume of the coil. A network-controlled rectifier (rectifier/inverter) connects the storage coil with the line. The operating state of the storage device (charging, discharging, storage) is set by controlling the firing angle of the thyristors (Fig. 32). In comparison with other energy storage means, SMES has the advantage of very short response times (< 100 ms), while larger storage devices have the further advantage of high efficiency (> 90 %). In addition, they can be used for several tasks in the grid simultaneously, such as peak handling, grid stabilization, and hot standby.

Figure 32. Operation of a superconducting magnetic energy storage (SMES) device
a) Transformer; b) Rectifier/inverter; c) Liquid nitrogen; d) Superconducting coil; e) Control; f) To three-phase grid

In the United States and Japan, where subsidiary grids are less well interconnected than in Europe, the discussion concerns the use of large storage units for peak-load storage (day/night

storage). Such devices, with power ratings in the 1000 MW range and capacity of several GWh, can compete with large pumped-storage hydro plants. Small and medium-sized storage units are being investigated as a means of improving grid stability (frequency, voltage, power fluctuations), smooth out shock loads, and serve as immediate standby sources. Their use with strongly fluctuating renewable energy sources (sun and wind) is also being studied.

Increased use of SMES in future grids may reduce the need for new plant construction and improve the utilization of existing fossil-fuel plants. This would yield an appreciable cut in fossil-fuel consumption and in the associated CO_2 emissions and other problems.

In 1991, development of a storage unit (100 kWh, 20 MW) for grid stabilization began in Japan. An Engineering Test Model (ETM) with a storage capacity of 20 MWh is under discussion in the United States. "Micro" SMES units (ca. 1 MW) are already being used to protect sensitive manufacturing equipment against voltage spikes.

The designs of large-scale storage units and experimental systems are based on metallic superconductors at 4.2 K. The use of HT superconductors at 77 K would have little effect on the capital costs of a storage unit but would improve the efficiency, even in large units (ca. +3 %). For small and medium-sized storage plants ($\leq$ 1 MWh), HT superconductors are an essential precondition for acceptable efficiency levels [73].

5.4.5. Superconducting Current Limiters

Increasing short-circuit currents in power grids impose steadily growing dynamic loads on integral components such as generators, transformers, and switchgear. Another idea is to use the fast ($\leq$ 1 ms) transition of superconductors from the superconducting to the normally conducting state (from $R \approx 0$ to very high R) to limit fault currents to acceptable values. The transition can be initiated spontaneously (when critical values are exceeded) or controlled externally (with pulsed supplemental current or supplemental magnetic field).

The three basic limiter concepts now being studied for three-phase grids are illustrated in Figure 33. In Figures 33 A and B, the superconductor is in the form of a wire or tape of well-defined length in a low-inductance configuration (e.g., a bifilar winding). In the resistive limiter (Fig. 33 A), the superconductor is connected in parallel with an ohmic resistance R_p kept at room temperature. When the superconducting winding (trigger coil) becomes normally conducting ($R_s >> R_p$), the current switches over to the parallel resistance R_p, which limits it to a predetermined value. After ca. 50 ms, the limited

Figure 33. Main types of superconducting current limiters (one phase shown)
A) Resistive; B) Hybrid; C) Inductive, SC = Superconductor; CB = Conventional breaker

current is interrupted by a conventional breaker. The resistive limiter is also well-suited to limiting direct currents. The hybrid type (Fig. 33 B) also has a low-inductance superconducting trigger coil, but here the current is limited by a choke (limiter coil), a high-inductance copper or superconductor winding connected in parallel with the trigger.

The inductive class (Fig. 33 C) has a number of variants, such as a normally conducting choke whose windings are shielded from its iron core by a cylinder made of massive superconducting material. In normal operation, the cylinder is superconducting and the inductance of the coil is very low. If a fault current causes the cylinder to become normally conducting, it loses its shielding action and the iron core of the choke becomes fully effective; the inductance of the coil increases abruptly and limits the current.

The feasibility of superconducting current limiters at medium voltages has been demonstrated with a number of small, single-phase experimental devices using metallic superconductors. In the most advanced project, the Japanese industry is collaborating with a large electric utility to develop a three-phase, 6 kV/2 kA limiter [74]. The use of the new HT superconductors is also being tested, because the simplicity of cooling with liquid nitrogen instead of helium should yield a decrease of ca. 70 % in the operating losses and savings of ca. 60 % for the cooling plant.

6. Organic Superconductors

6.1. Introduction

Molecular conductors differ fundamentally from the regular metallic conductors in that they are composed of building blocks (the molecules) that exhibit their own specific properties (e.g., molecular orbitals with their ionization energy or electron affinity, characteristic IR or Raman active modes, and NMR chemical shifts of different atomic sites). In contrast to conventional molecular crystals made up of neutral organic molecules held together by weak van der Waals forces, organic conductors contain molecules with unpaired carriers in π molecular orbitals (open shells) which allow delocalization over all molecular sites in the crystal via strong intermolecular π overlap. The open-shell character arises from partial oxidation (reduction) of donor (acceptor) molecules with formation of a salt of an inorganic anion (cation).

These molecular conductors are therefore different from the extended conjugated polymers and graphite where the π system of the extended molecules provides the conducting pathway.

The development of molecular conductors (superconductors) has been stimulated to a large extent by the suggestion made by LITTLE in 1964 [75] that the arrangement of chain conductors in a polarizable medium could give rise to superconductivity at high temperature.

The geometry of the building blocks governs the dimensionality of the transport properties of these particular conductors (between one and three dimensions).

For one-dimensional conductors, the planarity of the molecules is responsible for their particular crystal structure (Fig. 34 A). All these molecules are modifications of the flat fulvalene skeleton. Noticeable intermolecular overlap is allowed when they form stacks. The conduction band derives from π orbitals directed along the stacks and reveals a pronounced 1-D character, i.e., a flat and open Fermi surface [76, 77].

Higher dimensionality conductors are also derived from similar planar molecules that form dimers with strong overlap between chalogen atoms both within each dimer and between neighboring dimers (Fig. 34 B). This crystal structure gives rise to a large conductivity within molecular layers and to about 10^4-times less conduction between sheets. They can be considered as 2-D conductors [78].

The discovery of the spherical C_{60} molecule has opened the way to 3-D isotropic molecular conduction. Three of the four valence electrons of each carbon atom are engaged in sp^2 bonding with the three neighbors. There remains one electron per carbon atom in a p-state which is delocalized over the whole surface of the sphere in πmolecular orbitals. The neutral C_{60} molecule possesses a closed-shell electronic

Figure 34. Crystal structure of organic conductors
A) 1-D Conductor $(TMTSF)_2PF_6$ viewed perpendicularly to the high-conductivity axis; B) 2-D Conductor $(BEDT\text{-}TTF)_2Cu(SCN)_2$ viewed along axis of least conductivity; C) 3-D Conductor K_3C_{60}

structure, giving rise to an insulating molecular solid. However, populating the highest unoccupied molecular levels (the LUMO) with carriers donated by inorganic cations such as alkali or alkaline-earth metals gives rise to a partly filled conduction band. This band is half-filled in the prototype material A_3C_{60} (A = K, Rb, Cs, etc.). The C_{60} spheres are packed in a face-centered cubic lattice, leaving cavities with octahedral and tetrahedral local symmetry, which are all occupied in A_3C_{60} (Fig. 34 C) [79].

6.2. Electronic Structure and Superconductivity

The salts of the tetramethylselenafulvalene (TMTSF) molecule are regarded as prototype materials for 1-D molecular conductors. The overlap between organic stacks along the transverse *b*-direction amounts to $t_{\perp b} \approx 20-30$ meV, which is about one tenth the value for the intrastack overlap ($t_{\parallel} \approx 200-300$ meV), making the conduction band about 1 eV wide. The overlap is negligible along the *c*-direction. Such a marked anisotropy causes the Fermi surface to be nearly planar, intersecting the $k_{\parallel}$ axis at wave vectors $\pm k_F$, where the Fermi wave vector for a 1-D conductor is related to the density of carriers per unit cell ϱ by the relation $2k_F = \varrho\pi/a$ [80]. The stabilization of superconductivity below a certain critical temperature T_c requires overcoming the strong divergence that develops at low temperature in a 1-D electron gas towards an insulating behavior (see below).

$(TMTSF)_2PF_6$, the organic compound in which superconductivity was first observed [81], requires a pressure of 9 kbar. However, $(TMTSF)_2ClO_4$ is actually the only 1-D material that undergoes a transition to superconductivity at $T_c = 1.2$ K under ambient pressure. These temperature values are rather low, but higher T_c values are reached in materials where the shape of the Fermi surface is less likely to lead to the stabilization of insulating ground states (the 1-D and 2-D molecular superconductors, Fig. 35; see next page).

In 2-D conductors, the Fermi surface is tubular with $t_{(a,b)} = 100-150$ meV, $t_{\perp c} \approx 0.5$ meV, and consequently T_c rises up to 8.1 K in $(BEDT\text{-}TTF)_2I_3$ [bis(ethylenodithio) tetrathiafulvalene

Table 4. Properties of organic superconductors

Property ∗	Compound (dimensionality)		
	TM_2X (1-D)	$\varkappa$-ET_2X (2-D)	A_3C_{60} (3-D)
T_c, K	1.2 (X=ClO_4)	9 (X=Cu(SCN)$_2$); 12 (X=Cu[N(CN)$_2$]Br)	19 (A=K); 33 (A=Rb_2Cs)
H_{c1} (0 K), 10^{-4} T	0.2 (*a*); 1 (*b*); 10 (*c*)	1 (*a, b*); 45 (*c*)	
H_{c2} (0 K), T	2.8 (*a*); 2.1 (*b*); 0.16 (*c*)	30 (*a, b*); 2 (*c*)	49

and even up to 10 – 12 K for anions such as $Cu(SCN)_2^-$ and $Cu[N(CN)_2]Cl^-$ [78, 82].

Figure 35. The superconducting transition of 1-D (under pressure) and 2-D organic conductors

Like one- or two-dimensional molecular conductors, the conductivity in fullerenes is due to π overlap between organic molecules, counterions playing essentially no role in the conduction process. The shape of the molecules and the crystal structure make A_3C_{60} compounds three-dimensional conductors with a very narrow conduction band (≤ 0.5 eV) due to the weakness of the intermolecular interactions. Superconductivity ranges from 19 K in K_3C_{60} up to 28 K in Rb_3C_{60}. The highest T_c stabilized at the moment for a molecular conductor is 33 K in Cs_2RbC_{60} [79].

All these materials display the general features which are common to superconductors, namely a state with zero resistance and the expulsion of magnetic flux below T_c. They are type II superconductors: there exists a broad field range between H_{c1} and H_{c2} in which the magnetic field is not fully expelled from the material (the vortex state). For all organic conductors but the fullerenes, parameters describing the superconducting phase are strongly anisotropic (see Table 4 where TM and ET are abbreviations of TMTSF and BEDT-TTF, respectively).

Although the search for new superconductors has been the driving force in the study of molecular conductors, many more basic physical properties related to the low-dimensional character have been discovered and are discussed briefly in Section 6.3.

6.3. Other Features of 1-D Superconductors

The TM_2X Phase Diagram. A direct consequence of the 1-D character of the TM_2X series is the existence of a wide variety of ground states which can be observed in various members of the family depending on parameters such as the chemical composition of the organic molecule or of the inorganic counterion and also on hydrostatic pressure.

Figure 36 displays the variety of ground states; it is a generic diagram for the TM_2X family.

On the left of the diagram, TM_2X compounds exhibit a metal-like behavior at high temperature, but below the temperature $T\varrho$, where the resistivity passes through a broad minimum, a loss of the charge degree of freedom is observed, leaving the spins localized and behaving like those of a chain quantum antiferromagnet. Coulombic repulsions are responsible for such localization (Wigner-like localization) [83]. In the same temperature range the electron–phonon interaction gives rise to a 1-D

lattice fluctuation with a doubled periodicity which is detected by X-ray experiments. Below ca. 20 K these 1-D lattice fluctuations order themselves three-dimensionally and the system undergoes a phase transition with loss of the spin degrees of freedom. The ground state is a spin-Peierls (SP) phase in which the lattice is tetramerized and the spins are coupled in a singet state of total spin zero.

Figure 36. The generalized phase diagram for the TM_2X series
TMTTF = tetramethyltetrathiafulvalene;
TMDTDSF = tetramethyldithiadiselenafulvalene;
TMTSF = tetramethyltetraselenafulvalene
SP = Spin-Peierls; SDW = Spin density wave; SC = Superconducting ground states; CL = Region where charges are localized by Coulombic forces

As one moves toward the right-hand side of the diagram the role of the electron – phonon interaction becomes less dominant but electron – electron interactions remain important, as shown by the temperature dependence of the spin susceptibility, which is still strongly reminiscent of the 1-D antiferromagnet. In this region of the phase diagram the new order that becomes established below 19 – 12 K is characterized by a modulation of the spin density with a wave vector $\boldsymbol{Q}$ which provides the best nesting of the Q-1-D Fermi surface [80]. It is the presence of this additional periodicity in the exchange potential which is responsible for the opening of a gap $2\,\Delta$ at the Fermi level accompanied by a metal – insulator transition.

Finally, on the very right of the diagram, the spin density wave (SDW) ground state itself is suppressed by an enhanced transverse coupling and superconductivity becomes stable instead.

As far as the conducting phase is concerned, the electron gas cannot be regarded as an ordinary electron gas. Once more the one-dimensionality and the existence of strong electron – electron coulombic repulsions make this metallic state remarkable. In spite of a fairly high conductivity – reaching $10^6\,(\Omega\,\mathrm{cm})^{-1}$ at low temperature for the compounds in the $(TMTSF)_2X$ series – the susceptibility of the conducting state develops a strong tendency toward antiferromagnetism at low temperature. As shown by NMR experiments, the antiferromagnetic response becomes prominent below 150 K and displays a power law divergence $\chi_S \approx (T/E_F)^{-\gamma}$ with $\gamma \approx 0.85$ as expected from the theory of the 1-D correlated electron gas. On the other hand, the uniform spin susceptibility measured by a Faraday technique is temperature dependent, very much like that of a 1-D quantum antiferromagnet. Therefore, the superconducting instability of $(TMTSF)_2X$ conductors arises out of a background of antiferromagnetic fluctuations.

Spin Density Wave Collective Conduction. The antiferromagnetic state of Figure 36 also exhibits various novel physical properties. It is the nesting of the Fermi surface with the wave vector $\boldsymbol{Q}$ which drives the transition from a metal at $T > 12$ K in $(TMTSF)_2PF_6$ to an insulator exhibiting a magnetic modulation or spin density wave at the same wave vector $\boldsymbol{Q}$.

The broken symmetry of the SDW ground state, characterized by a magnetic modulation at wave vector $\boldsymbol{Q}$ in $(TMTSF)_2X$, $X = PF_6$, NO_3 etc., is responsible for the activated behavior of the conductivity through the single particle gap $2\,\Delta$. Moreover, two kinds of collective excitation arise in the SDW condensate. These are the magnon excitations, which manifest themselves in the antiferromagnetic resonance, and the phase mode of the condensate which is gapless provided the spin modulation is non-commensurate with the underlying lattice. In $(TMTSF)_2PF_6$, the wave-vector corresponding to the optimum nesting of the Fermi surface is incommensurate, as shown by various measurements sensitive to local magnetic fields. There-

fore, as long as $\boldsymbol{Q}$ is incommensurate with the underlying lattice the electrons can slide freely without any cost in energy, almost like in a superconductor. However, in real materials the interaction between a SDW (or the associated CDW) and impurities or crystal defects provides a finite pinning energy, and a threshold electric field E_T must be reached before the condensate can contribute to the conduction at zero frequency (Fig. 37). In all SDW phases of the $(TMTSF)_2X$ series E_T is restricted to the range of a few mV/cm [84]. Furthermore, the linear increase of E_T versus the density of lattice defects suggests that the phase of the spin modulation is locally adjusted at each defect site to provide the largest pinning energy (strong pinning limit).

Figure 37. Current – voltage characteristics in the SDW state showing the onset of nonlinear conduction due to the collective motion of the entire electron gas above a threshold field E_T

Direct evidence for spin density wave transport is the detection of a current oscillating at a frequency proportional to the d.c. current carried collectively. The observation of such oscillations, the harmonic and sub-harmonic locking of this oscillation to an external a.c. source and a motional narrowing of the NMR spectrum in the sliding SDW state have provided firm evidence for the existence of a novel collective transport in the SDW condensate [85].

Quasi-1-D Electrons in High Magnetic Fields. The response of the Q-1-D electron gas to the application of a strong magnetic field has provided new and unexpected results, namely the transition from a Q-1-D conductor to a quasi-2-D antiferromagnetic semimetal induced by a magnetic field at low temperature. The instability of the Q-1-D electron gas at high field can be inferred from the observation of magnetoresistance oscillations above a certain threshold field in $(TMTSF)_2PF_6$ under pressure. Moreover, NMR data have shown that the ground state, which is stabilized by the magnetic field, is characterized by the existence of a spin density wave.

These phenomena are fairly well explained by a model in which, crudely speaking, the field restores enough one-dimensional character in the energy dispersion for the SDW distortion to become stable at a finite temperature [86]. This is also equivalent to the effect of negative pressure. However, the experimental data of $(TMTSF)_2PF_6$ show that the effect of the magnetic field is slightly more sophisticated. A sequence of phases must be crossed before the so-called $N = 0$ phase (which is believed to correspond to the insulating SDW ground state, which is stable at ambient pressure) can be reached above 18 T (Fig. 38 A) [87]. The integer N is related to the deviation of $\boldsymbol{Q}_x$ from $2\,k_F$, and denotes a phase containing N fully occupied Landau levels, quantized by the magnetic field. The situation $N = 0$ corresponds to zero density of states at the Fermi level, i.e., a gap which is opened over the whole Fermi surface. Phases with $N = 1, 2, 3, \ldots$, which are observed below 18 T, correspond to a sequence of semimetallic phases with a very low density of carriers (ca. 10^{-2}/unit cell). In these subphases 1, 2, or 3, ... Landau levels are completely filled. The situation where the Fermi level falls between completely filled and completely empty levels minimizes the diamagnetic energy of the 2-D carriers. This situation prevails in a finite range of magnetic fields, and the wavevector of the magnetic modulation within a given subphase can vary linearly with the field. First-order phase transitions are expected between various subphases, in agreement with the observation of hysteresis, as shown in Figure 38. The quantization of the Hall resistance at $\varrho_{xy} = h/2\,Ne^2$ (where the factor 2 comes from the spin degeneracy) is a direct consequence of the field dependence of the $\boldsymbol{Q}$ vector. The $(TMTSF)_2PF_6$ Hall data (Fig. 38 B) agree very well with the quantized nesting theory [88]

The quantization of the Hall resistance in the field-induced SDW (FISDW) phases is indeed very reminiscent of the quantum Hall ef-

Figure 38. Temperature versus magnetic field phase diagram (A) and quantized Hall resistance (B) for $(TMTSF)_2PF_6$ under pressure

fect of the 2-D electron gas in semiconducting heterostructures. There is, however, an important difference between these two phenomena. In both cases the quantization requires a reservoir of nonconducting electronic states. This reservoir is provided by localized states in the gap between conducting Landau levels or the electron – hole (spin modulation) condensate for the 2-D electron gas and the FISDW, respectively.

6.4. Prospects for Higher T_c and Applications

Molecular superconductors are still in their infancy, but they have already demonstrated their capability to exhibit superconductivity at temperatures higher than those of any other inorganic materials apart from the high T_c cuprates. Although the mechanism for superconductivity has not been clearly identified, some guide lines have already emerged from the study of the known compounds.

As far as 1-D conductors are concerned the effectiveness of the on-site Coulombic repulsion is enhanced by the nesting properties of the Fermi surface. The resulting competition between the Cooper and Peierls channels is particularly damaging for superconductivity which cannot be stabilized above ca. 1 K in 1-D conductors derived from the TTF skeleton.

This competition is, however, less severe in 2-D materials where consequently T_c can be raised up to 12 K. Attempts to increase T_c by further decreasing the intermolecular overlap [and thus increasing $N(E_F)$] using more bulky inorganic ions have failed to provide metal-like materials, but compounds with interesting magnetic properties have been obtained.

The fullerenes, in which superconductivity is presumably mediated by high energy intraball vibrations, represent a good compromise between a weak interball interaction and the on-site Coulombic repulsion which is sufficiently small to prevent the stabilization of an insulating Wigner crystal.

The applications of the superconducting properties are still very much dependent on material preparation. However, when large areas of organic superconductors become available it may be possible to use arrays of Josephson circuits prepared by lithographic techniques to build low current devices such as high-density memories and microwave detectors.

The very narrow electronic paramagnetic resonance of some organic conductors can be used in sensitive magnetic sensors [89].

1. Interfacial Phenomena [9-11]

Forces holding the particles of a condensed phase together (cohesive forces) become anisotropic in the phase boundary region, and their normal component becomes smaller compared to the parallel component. To simplify the description and facilitate theoretical treatment, the properties of the boundary region of a condensed phase are projected onto a two-dimensional surface (Gibbs "dividing surface"). The tensile stress resulting from the anisotropic forces in the boundary region is then termed the interfacial tension. This quantity corresponds to the reversible work required to bring particles from the volume phase to the interface during enlargement of the former, and thus corresponds to the increase in free enthalpy of the system per unit surface area:

$$\left(\frac{dG}{dF}\right)_{P,T} = \gamma$$

where *G* is the free enthalpy, *F* the surface area, and γ the interfacial tension.

The unit of interfacial tension is accordingly N · m/m^2, i.e., N/m, and is normally expressed as mN/m. The interfacial tension in most cases decreases with increasing temperature and with increasing pressure.

Interfaces exist between all contacting but immiscible phases; in current usage the term interface is understood to mean the contact region of two condensed phases, whereas the term surface refers to the boundary region between a condensed phase and a gas. Surface tensions of liquids and interfacial tensions between two liquid phases can easily be measured. The capillary rise of a liquid in a capillary tube can be used to calculate the surface tension of a liquid if the walls of the capillary tube are completely wetted by the liquid (capillary attraction).

The value of γ can be obtained directly by measurement of the force required to enlarge the surface or interface between two liquids over a specific length. A small wettable measuring plate (Wilhelmy plate) or a ring slowly withdrawn from the liquid (Lecomte du Noüy tensiometer) is used for this purpose. In the droplet-volume method the volume of a droplet released from a capillary tube, which is directly proportional to the interfacial tension, is measured. The surface tension of a liquid can also be determined by measuring the maximum pressure in air bubbles forced through a capillary tube into a liquid, this pressure being directly proportional to the surface tension. Extremely low interfacial tensions in the range from 10^{-1} to 10^{-5} mN/m can be measured with a spinning drop tensiometer, in which a droplet of the lighter phase is suspended in the heavier liquid contained in a rotating capillary [12], [13]. Also, capillary wave spectroscopy is used to measure the interfacial tension between two liquids [14].

In the equilibrium state only very small energy interactions occur between the particles at the surface of a condensed phase and those of the gaseous phase. The surface tension can therefore be regarded simply as an expression of the interactions between the particles in the surface of the condensed phase. However, at the interface between two condensed phases interactions between the particles of the two phases occur through the interface, resulting in a reduction of the interfacial tension. When examining the interactions between the particles of condensed phases a distinction has to be made between London dispersion forces and polar forces. Accordingly, the surface tension comprises components that may be attributed to pure dispersion forces (γ_d) and to polar interaction (γ_p):

$$\gamma = \gamma_d + \gamma_p$$

For example, water has a surface tension of 72.8 mN/m, composed of 21.8 mN/m for γ_d and 51.0 mN/m for γ_p.

In contrast, alkanes and also polyethylene have no surface tension attributable to polar forces, and in this case $\gamma = \gamma_d$. If one of the phases at an interface is completely nonpolar, then the interaction through the interface is restricted to dispersion forces and the interfacial tension between two condensed phases is given by Fowkes equation:

$$\gamma_{12} = \gamma_1 + \gamma_2 - 2\sqrt{\gamma_{d1}\gamma_{d2}}$$

The equation includes the polar component of the surface tension if polar interactions also act through the interface:

$$\gamma_{12} = \gamma_1 + \gamma_2 - 2\left(\sqrt{\gamma_{d1}\gamma_{d2}} + \sqrt{\gamma_{p1}\gamma_{p2}}\right)$$

If a droplet of a liquid is brought into contact with the surface of a first liquid — the two liquids being immiscible — two phenomena can occur, depending on the magnitude of γ_{12}. If γ_{12} is smaller than ($\gamma_1 - \gamma_2$), the second liquid spreads over the surface of the first liquid in the form of a thin (in the limiting case monomolecular) film. The liquid that has spread exerts a surface pressure π in the opposite direction to the surface tension γ_1 of the underlying phase, resulting in a reduced surface tension γ'_1 of this phase:

$$\gamma_1 - \pi = \gamma_1'$$

The surface tension γ'_1 can be measured by the aforementioned methods, and the surface pressure π by a Langmuir surface balance, which measures the force acting on a barrier that restricts the spreading film. If the particles of the spread liquid are sufficiently far apart, the liquid film behaves as a two-dimensional gas described by the equation of state:

$$\gamma F = RT$$

where *F* is the available surface, *R* the gas constant, and *T* the temperature. Such a surface film is elastic. If the film is compressed, a region characterized by a sharp increase in surface pressure is reached since the forces of repulsion between the particles then come into play. This region corresponds to the state of a condensed liquid. On compressing the surface film further the latter may finally break up due to furrow formation, layer stacking, etc., whereupon the surface pressure decreases.

If the interfacial tension γ_{12} between a first liquid having a surface tension γ_1 and a second liquid having a surface tension γ_2 applied as a droplet to the surface of the first liquid is greater than ($\gamma_1 - \gamma_2$), the applied droplet remains in the form of a lens in the surface of the underlying liquid (Fig. 1). The forces resulting from the two surface tensions γ_1 and γ_2, as well as from the interfacial tension γ_{12}, act at the point of contact of the two liquid phases with the gas phase. If the resultant angles α, β, and ϕ are measured and two of the tensions are known, the third can be calculated (Neumann triangle). If the underlying phase 1 is a solid and its surface is not deformed, then γ_1 and γ_2 act in opposite directions along a straight line, and the contact or wetting angle ϕ between the applied liquid and the surface of the solid is formed at the point of contact of the three phases (Fig. 2). The contact angle ϕ is given by Young's equation:

$$\cos\phi = \frac{\gamma_1 - \gamma_{12}}{\gamma_2}$$

Figure 1. Lens formed by a nonspreading liquid 2 on another liquid 1 (schematic)

Figure 2. Formation of a contact (wetting) angle ϕ between a liquid 2 and a solid surface 1 (schematic)

The contact angle can be measured by direct observation of a droplet on a horizontally mounted plate of the solid. If the liquid is advancing the contact angle generally becomes larger than in the stationary state on account of the restricted elasticity of the liquid and the roughness of the solid surface, and if the liquid is receding the contact angle becomes smaller (Fig. 3).

Figure 3. Contact angle ϕ of a liquid on a solid surface in the advancing state (a) and receding state (r) (diagrammatic)

The determination of the contact angle is important for evaluating the wetting of solids and for indirect determination of the surface tension γ_1 of a solid. The nonpolar and polar components of the surface tension of the solid must be determined separately by measuring the contact angles with nonpolar and polar liquids which are then added to obtain the total surface tension. The surface tension γ_1 of the solid employed in Young's equation accordingly corresponds only to the force resulting from the effective interactions (γ_{12}) between liquid and solid on the one hand, and the surface tension of the liquid (γ_2) on the other. This surface tension γ_1 therefore generally does not correspond to the true surface tension of the solid, but only to a part thereof.

The reversible work per unit area that is exchanged with the surroundings in the formation of a liquid – solid interface is the adhesion or wetting tension γ_j, which expresses the adhesion forces between liquid and solid surface:

$$\gamma_j = -\gamma_2 \cos\phi = \gamma_{12} - \gamma_1$$

If the solid is wetted by the liquid the adhesion tension is negative (ϕ < 90°), whereas if it is not wetted the tension is positive (ϕ > 90°). For example, the adhesion tension

between water and glass is negative, i.e., energy is released to the surroundings on formation of the interface, and the contact angle is < 90°. Thus water wets glass and rises in a glass capillary. In contrast, the adhesion tension between water and polyethylene is positive, i.e., work must be expended to produce a water – polyethylene interface, and the contact angle is > 90°. Hence water does not wet polyethylene completely and is displaced from a polyethylene capillary.

The wetting of a solid surface by a liquid is analogous to the spreading of a substance on a liquid surface.

The afore-described phenomena are observed for phases of a pure substance and for multicomponent phases. In the latter case, as a result of anisotropic interactions in the boundary region of a condensed phase, accumulation or depletion of components in this region may occur (positive or negative adsorption at the interface). Substances that accumulate from a liquid phase at the interface (or surface) are referred to as interface-active, usually as surface-active or, more loosely, capillary-active; substances that accumulate in the volume phase, rather than at the interface, are accordingly termed inactive.

Interfacial activity leads to a decrease of the interfacial tension compared to that of the pure substance, whereas interfacial inactivity increases the interfacial tension. Most water-soluble organic substances lower the interfacial and surface tensions of water, whereas inorganic salts increase them. For example, 20 wt % of butyric acid reduces the surface tension of water from 73 to 27 mN/m, whereas the addition of 20 wt % of water to pure butyric acid does not reduce the surface tension of butyric acid of 27 mN/m. Thus butyric acid is surface-active in water, but water is not surface-active in butyric acid. A 10 % sodium chloride solution has a surface tension that is 3 mN/m higher than that of pure water; the strongly hydrated sodium chloride ions in the volume phase are surface-inactive.

Strong accumulation of substances at the interface is termed adsorption. The adsorption of substances from a liquid phase at its interface is described by the Gibbs equation:

$$-\frac{d\gamma}{d\ \ln c} = \frac{\Gamma RT}{x}$$

where γ denotes the surface tension, c the concentration of a substance in the volume phase in mol/cm^3, Γ the excess concentration of this substance in the interface over the concentration in the volume phase in mol/cm^2, R the gas constant, T the temperature, and x is a correction factor between 1 and 2 that depends on the degree of dissociation of the adsorbed substance. For nondissociated substances $x = 1$, and for completely dissociated substances $x = 2$.

If Γ is negative, i.e., if the concentration of a dissolved substance in the interface is lower than in the volume phase, the interfacial and surface tensions increase, whereas if Γ is positive, which means a higher concentration of the dissolved substance in the interface than in the volume phase, the interfacial and surface tensions of the condensed phase decrease with increasing concentration of the dissolved substance in the volume phase. The greater the excess concentration Γ of a substance at the interface, the more strongly surface-active it is. Surfactants, also referred to as tensides, are active substances whose molecules or ions have the property that when a characteristic concentration in aqueous solution is exceeded, they associate by reversible aggregation to form larger particles, known as micelles, which impart colloidal behavior to the solution.

The reason for the large adsorption at the interface lies in the chemical structure of the adsorbed substance. Surfactants are amphiphilic substances: their molecules contain endophilic and exophilic groups. Endophilic groups are those that interact strongly with the condensed phase, whereas exophilic groups are those that interact more strongly with one another than with the volume phase, and are therefore expelled from the latter. With amphiphilic substances the exophilic group is forced out of the volume phase and the endophilic group is drawn in, an accumulation in the form of an oriented adsorption occurrs at the interface. In aqueous systems the endophilic groups are termed hydrophilic, and the exophilic groups are termed hydrophobic.

In addition to the interfacial phenomena, which can be described with the aid of thermodynamics, electrical potentials are generally produced between condensed phases in ionizable systems. By dissociation, adsorption, desorption, and exchange of ions in the interface, an electrical double layer is formed consisting of two components: a relatively rigid adsorption layer and a diffuse component that extends to a greater or lesser extent into the volume phase, depending on the ionic strength. The electrical potential of the rigid adsorption layer (Stern potential) can be determined approximately by electrophoresis or flow potential measurements (zeta potential [15]).

[Top of Page]

2. Overview of Surfactants

The highly diagrammatic tail – head model is widely used in the graphical representation of simple surfactants; the tail symbolizes the hydrophobic group, and the head the hydrophilic group.

The hydrophobic groups are mainly alkyl or alkylaryl hydrocarbon groups, but fluoroalkyl, silaalkyl, thiaalkyl, oxaalkyl groups, etc., are also possible. Some important hydrophobic and hydrophilic groups are listed below:

Hydrophobic groups	Hydrophilic groups
$C_nH_{2n+1}-$	$-COO^-K^+$
$C_nH_{2n-1}-$	$-SO_3^-Na^+$
$C_nH_{2n+1}-C_6H_4-$	$-PO_3^{2-}2Na^+$
$C_nF_{2n+1}-$	$-OSO_3^-Na^+$
$CH_3-[SiO(CH_3)_2]_n-$	$-OPO_3^{2-}2Na^+$
	$-(OCH_2CH_2)_nOSO_3^-NH_4^+$
	$-(OCH_2CH_2)_n-OH$
	$-CON[(OCH_2CH_2O)_nOH]_2$
			$-N(CH_3)_2 \longrightarrow O$
	$-NR_3^+Cl^-$
	$-PR_3^+Cl^-$
	$-SR_2^+Cl^-$
	$-\overset{+}{N}(CH_3)_2CH_2COO^-$

Since surfactants mainly act in aqueous systems, it is expedient to classify surfactants according to the chemical structure of their hydrophilic groups. The hydrophilic groups may be ionic or nonionic, and their chemical structure can vary widely.

The following classification of surfactants has proved convenient (arranged in order of industrial importance).

Anionic surfactants, anionics, anion-active compounds, are amphiphilic compounds in which the hydrophobic residues carry anionic groups with small counterions such as sodium, potassium, or ammonium ions which only slightly influence the surface-active properties of the substance. Examples include soaps, alkylbenzenesulfonates, alkyl sulfates, and alkyl phosphates.

Nonionic surfactants, niosurfactants, are amphiphilic compounds that are unable to dissociate into ions in aqueous solution, for example, alkyl and alkylphenyl polyethylene

glycol ethers, fatty acid alkylolamides, sucrose fatty acid esters, alkyl polyglucosides, or trialkylamine oxides.

Cationic surfactants, cationics, cation-active compounds, are amphiphilic compounds in which the hydrophobic residues exist as cations with counterions such as chloride, sulfate, or acetate that only slightly influence the active properties of the compound. Examples include tetraalkyl ammonium chloride or *N*-alkylpyridinium chloride.

Amphoteric surfactants, amphosurfactants, (i.e., ampholytes and betaines) have zwitterionic hydrophilic groups. Examples include aminocarboxylic acids, betaines, and sulfobetaines:

The electrical charge state of the amphosurfactants, which are often sparingly soluble at the isoelectric point, depends on the pH of the solution.

The subdivision of surfactants according to this classification is sometimes unambiguous. Nonionic surfactants may assume a cationic character in acid solution due to protonation; amine oxides are an example of this:

Anion – cation surfactants, in which anions and cations are amphiphilic and which are obtained by mixing anion and cation surfactants, are a special case. They are often sparingly soluble in water and in their properties resemble nonionic surfactants rather than ionic surfactants.

The structures of surfactants are not restricted to the simple tail – head model. Surfactants may contain several hydrophilic or hydrophobic groups. Examples include the sodium salts of the dialkyl sulfosuccinates:

with a hydrophilic group flanked by two hydrophobic groups, or the disodium salt of 1,14-disulfatotetradecane with two hydrophilic groups at both ends of a long hydrophobic residue:

Surfactants of the latter type are also termed bola surfactants.

Industrial surfactants [8] are not pure defined substances, but mixtures of a large number of isomeric, homologous, and chemically similar substances. Low molecular mass products account for the bulk of the industrial products. Amphiphilic higher molecular mass compounds also have surface-active properties and are produced for numerous special applications. Examples include sulfated or ethoxylated condensation products of alkylphenols and formaldehyde, ethylene oxide – proylene oxide block copolymers, modified polysiloxanes, polyvinyl-*N*-alkylpyridinium salts, or copolymers of vinyl pyridine and methacrylic acid, the last-mentioned being an example of polymeric amphosurfactants. The “polysoaps” combine polymeric cations (e.g., the cation of polyvinylpyridine) with fatty acid anions.

In the theoretical treatment of surfactants the demarcation with respect to other amphiphiles that form higher ordered aggregates such as vesicles or membranes but not micelles is not always sharp [16], [17]. Substances such as polar lipids or water-soluble proteins play an extremely important role in the physiological processes of living organisms [18].

The vast majority of surfactants have hydrophobic groups derived from hydrocarbons. Only a few groups of surfactants bear hydrophobic residues containing heteroatoms. Hydrocarbon-derived surfactants are discussed here according to the nature of their hydrophilic groups (anionic, nonionic, cationic, amphoteric); the remaining surfactants are treated according to the structural features of their hydrophobic groups (polypropylene glycol derivatives, silicone-based surfactants, fluorosurfactants).

The so- called biosurfactants produced by microorganisms, are treated in [19]; for high polymer surfactants, see [20].

[Top of Page]

3. Properties of Aqueous Surfactant Solutions [21-23]

In highly dilute aqueous solutions surfactants exist in monodisperse form and are concentrated at the interfaces by hydrophilic – hydrophobic oriented adsorption. The surface concentration Γ of a surfactant can be calculated from the Gibbs equation by measuring the surface tension as a function of the volume concentration (see Chap. Interfacial Phenomena). With a rise in volume concentration the surface concentration increases until the surface is completely covered by the surfactant molecules or ions. Further surfactant particles cannot be accommodated at the surface and Gibbs' equation is no longer valid. The area requirement of a surfactant molecule or ion in the adsorption layer can be calculated from the surface concentration at maximum occupancy. Such calculations show that the surfactant molecules are adsorbed with their longitudinal axis perpendicular to the surface. The projection of the largest surface-parallel cross section of the surfactant particle onto the surface gives its area requirement.

An entropy effect is extremely important for the interfacial activity. The hydrophobic groups of the surfactant molecules or ions are hydrophobically solvated in aqueous solution. Thus the water molecules are highly ordered in the immediate vicinity of the hydrophobic species, which is associated with a decrease in entropy. If the hydrophobic group is displaced from the aqueous phase, the state of disorder of the water and thus the entropy of the system increases. This effect is also termed the hydrophobic effect. If, under total occupancy of the surface, the volume concentration of the surfactant in equilibrium with the surface concentration prevailing in this case is exceeded, the surfactant molecules or ions, which up to this concentration are mainly present in the volume phase in monodisperse form, congregate in an entropy-governed manner to form larger aggregates (micelles) in which they are oriented with the hydrophilic groups pointing towards the aqueous volume phase and the hydrophobic groups towards the interior of the micelles.

The aggregation of surfactant molecules or ions into micelles takes place in a strictly limited concentration range characteristic of each surfactant; if the surfactant concentration rises further, the number of micelles per unit volume increases, but not, however, the number of monodisperse – dissolved surfactant molecules or ions (more correctly, their activity). Since micelle formation occurs at the volume concentration of the surfactant at which the surface is largely, if not completely, covered so that the surface tension becomes independent of any increase in volume concentration, measurement of the surface tension as a function of the concentration represents a simple method of determining the so- called critical micelle concentration (CMC) at which micellization or micelle formation begins (Fig. 4).

Figure 4. Surface tension Γ as a function of concentration *c*, and critical micelle concentration (CMC)

a) Nonionic surfactant (dodecylheptaglycol ether) in water; b) Ionic surfactant (dodecyl sulfate) in water; c) Dodecyl sulfate in 0.1 N sodium chloride solution

The increase in the number of particles in a surfactant solution with concentration suddenly drops at the critical micelle concentration due to micelle formation, and consequently the concentration dependence of all colligative properties such as vapor pressure and osmotic pressure, and in the case of ionic surfactants also the equivalent conductance, changes at this concentration.

Micelles are dynamic structures that are in equilibrium with the surrounding monodisperse surfactant solution; their average aggregation number fluctuates in purely aqueous solutions at the critical micelle concentration around a mean value characteristic of each surfactant. This value is between 100 and 1000 in simple nonionic surfactants, and is generally below 100 in ionic surfactants; with the latter, the electrostatic repulsion acting between the ionic head groups opposes further aggregation.

Above the CMC surfactant solutions are colloidal solutions; the surfactants form “association colloids” and behave like sols, and at higher concentrations behave like gels. This behavior is connected with the shape of the micelles that form under particular conditions. A distinction is made between spherical, rod-shaped, and disk-shaped micelles [24].

The shape of the micelle is determined primarily by the ratio of the area requirement of the head group of the surfactant under the prevailing conditions to the volume of the hydrophobic tail group. If this ratio is large, for example in the case of ionic *n*-alkyl surfactants, spherical micelles are formed. For small ratios, such as in the case of nonionic

alkyl polyglycol ethers, rod-shaped micelles are formed. However, simple ionic surfactants too can aggregate to form rod-shaped micelles if the electrostatic repulsion of the head groups is screened by adding an electrolyte and their spatial requirement on the surface of the micelle is reduced.

Surfactants with voluminous or several hydrophobic groups, as well as fluorosurfactants, form disk-shaped micelles. Some micelles as constituents of lyotropic mesophases are illustrated schematically in Figure 5.

Figure 5. Structure of lyotropic mesophases formed from micellar aggregates [24] (reproduced from [6], with permission)

A) Cubic phase; B) Hexagonal phase; C) Lamellar phase; D) Inverse hexagonal phase; E) Nematic rod phase; F) Nematic disc phase

Spherical micelles can transform at higher surfactant concentrations into rod-shaped or disk-shaped micelles. Such a transition may be indicated by a second critical micelle concentration, at which the colligative properties of the solution once more change abruptly.

At higher surfactant concentrations spatially extensive, ordered structures, known as liquid crystal mesophases or lyotropic liquid crystals, are formed. In a number of nonionic surfactants of the poly(ethylene glycol) ether type such liquid crystal phases can be attributed to the formation of specific hydrates [25].

Provided they do not transform into rod-shaped or disk-shaped micelles, spherical micelles condense into cubic phases, rod-shaped micelles into hexagonal phases, and disk-shaped micelles into lamellar phases, whose basic structure resembles the bilayer lipid membranes (BLM) of living organisms. The bilayer structures present in lamellar phases transform under high shear forces (e.g., by ultrasound) into vesicles — namely spherical structures having an outer bilayer membrane (Fig. 6) [26-28]. This structure was first observed in natural fat particles (liposomes), formed from lipids.

Figure 6. From bilayer lipid membranes (BLM) to vesicles

A) Amphiphilic molecule; B) BLM (section); C) Myelin structure; D) Partially broken myelin structure; E) Cross section through a vesicle (from [26], with permission)

The ordered and oriented, monolayer and multilayer adsorption of surfactants or amphiphiles leads to the formation of Langmuir – Blodgett films [29], which are important in surface treatment and coating technology.

Solutions of spherical micelles and cubic phases formed therefrom are isotropic, whereas solutions of rod-shaped and disk-shaped micelles and their liquid crystal phases are anisotropic. Due to this anisotropy the flow of surfactant sols and gels deviates from Newtonian behavior. A knowledge of this divergence from Newtonian flow is important in the preparation and formulation of surfactants, and in the design of pipelines and conveying and mixing equipment. A distinction is made between *pseudoplasticity* (shear thinning), namely decreasing in viscosity with increasing shear rate; and *dilatancy* (shear thickening), namely increasing viscosity with increasing shear.

When the mechanical stress is released pseudoplastic and dilatant liquids return to their original state.

Thixotropy is a decrease in viscosity as a result of sustained mechanical stress, and *rheopexy* an increase in viscosity as a result of sustained mechanical stress. The terms thixotropy and rheopexy imply that the liquids return to their original state, even after a time delay, when the mechanical stress is released; in practice, however, both expressions are used even if this is not the case.

Gels can also exhibit plastic behavior, acting as elastic solids below a certain critical shear stress (the yield stress or yield point) and transforming into the liquid Newtonian or non-Newtonian state only when the yield stress is exceeded.

Pseudoplasticity, thixotropy, and plasticity are often observed in surfactant solutions, whereas dilatancy and rheopexy occur less often. The flow behavior of surfactant solutions depends largely on the temperature, concentration, and on the presence of other additives, especially electrolytes. Transitions from one flow behavior to another are often produced by slight changes in the conditions, which must be taken into account when diluting or mixing surfactant solutions. The “thickening” of surfactant solutions, e.g., of alkyl polyethylene glycol ether sulfate solutions with sodium chloride is utilized in the formulation of such solutions. Conversely, the addition of a number of compounds such as urea or short- chain alkylbenzene sulfonates leads to the dissociation of the gel structure and thus decreased viscosity. Such substances are termed hydrotropics, and the effect, hydrotropy.

In addition to being viscous, many surfactant solutions at relatively high concentrations, exhibit limited elastic deformation, which is mainifested *inter alia* in vibrational phenomena. The flow behavior of such liquids is termed viscoelastic [30].

The flow behavior of surfactant solutions is measured in rotational viscometers (⟶ Rheometry). The solution is added to the gap between two concentric cylinders, one of which is at rest, while the other rotates. A shear rate gradient is generated due to the relative movement of the cylinders. The torque necessary for this movement is measured, from which the shear stress and viscosity of the solution are calculated. The cone-and-plate system is based on the same principle. A cone having an obtuse angle rotates over a plate and the liquid is subjected to shear forces in the gap between cone and plate.

Surfactant sols and gels often exhibit segregation phenomena. Coacervation is the separation of an initially uniform phase into two phases, one of which contains more of the colloidal component, and the other less. A further property of sols and gels is aging, known as deswelling or syneresis, i.e., the coagulation of gel particles and their dehydration, with the formation of a compacted gelatinous mass and a low- colloid liquid phase. To prevent such segregations, which can lead to difficulties in the storage and metering of surfactant solutions, mixing equipment must often be provided in storage vessels.

The fact that dissolved surfactants are adsorbed at interfaces and form micelles confers a number of properties on their solutions, which are described below.

Wetting. The formation of a liquid – solid interface inplace of a gas – solid interface is termed wetting. Young's equation describes the relevant relationships (see Interfacial Phenomena). A prerequisite, however, is that the surface-active substances are adsorbed at the interface so that their hydrophilic groups are directed towards the aqueous phase. If these hydrophilic groups are adsorbed on the solid surface and the hydrophobic groups project into the aqueous phase (inverse adsorption), the solid surface becomes hydrophobic, an effect that is exploited in water-repellent textiles, fabric softeners, and ore flotation, for example.

Rewetting. If a liquid, in particular a surfactant solution, displaces a liquid droplet or a solid particle insoluble in the latter from the surface of a solid, with emulsification or suspension of the displaced substrate, this is termed rewetting.

Solubilization is the apparent dissolution of substances that are insoluble or slightly soluble in water, in a surfactant solution by incorporation into the micelles. On the other hand, water can be solubilized in hydrophobic solvents by adding surfactants. Thereby, inverse micelles are formed, with the hydrophobic groups aligned outward and the hydrophilic groups inward (see Fig. 5D). Solubilization, like the decrease in surface tension and interfacial tension, is regarded as a characteristic property of surfactants in aqueous solutions.

Emulsion stabilization (see also ⟶ Emulsions) is the stabilization of disperse systems of two liquids that are insoluble or only slightly soluble in one another. This stabilization is based on covering the interfaces with surfactants that counteract coalescence of the droplets of the disperse phase. Such emulsions are metastable systems, and are also termed macroemulsions to distinguish them from the thermodynamically stable microemulsions [31-33].

Suspension stabilization is the prevention of coagulation and delay of sedimentation of solids finely dispersed in a liquid. The surfactants are solid – liquid adsorbed at the phase interface and prevent the aggregation and coagulation of the dispersed solid particles by means of steric screening and, in the case of ionic surfactants, also by electrostatic repulsion. Furthermore, under certain conditions surfactants are also able to deflocculate, without mechanical action, suspensions that have coagulated.

Protective colloid action is the suspension stabilization of hydrophobic colloids, especially against the coagulating action of inorganic salts.

Lime Soap Dispersion. A number of surfactants having relatively large or several hydrophilic groups can disperse sparingly soluble calcium and magnesium salts of fatty acids (lime soaps) in water. Examples of such surfactants include:

$$C_9H_{19} - C_6H_4 - (OCH_2CH_2)_{10} - OH$$

$C_{17}H_{35}CONH(CH_2)_3N^+(CH_3)_2(CH_2)_3SO_3^-$

$C_{10}H_{21} - C_6H_4 - SO_2NHCH_2CH_2SO_3Na$

Foams (see also ⟶ Foams and Foam Control). Surfactants accumulate at the interface of a gas bubble in aqueous solution, with their hydrophobic residues directed to the interior of the bubble. When the ascending bubble bursts through the surface of the liquid phase the film of surfactants present there becomes attached to the surface of the bubble. A lamella consisting of two films of surface-active substance is obtained, with hydrophilic groups pointing into the interior of the lamella and hydrophobic groups pointing away from the lamella. Liquid entrained from the solution is found between the films. The combination of numerous such bubbles constitutes a foam. The properties of foams are connected with the mechanical properties of the lamellae and the dynamic processes in and on the lamellae (viscosities of the surface films and interlamellar liquid, elasticity of the surface films, diffusion and spreading rate of the surface-active substances, electrical repulsion, Van der Waals attraction between the two films of the lamella, and gas permeability, leading to drying and breaking of the lamella).

The properties of surfactant solutions are the result of adsorption and aggregation of the surfactant molecules and ions; the attainment of the equilibrium state is determined by the rate of diffusion, orientation, and organization of the surfactant molecules and ions. Many properties of surfactant solutions are therefore *time-dependent.* The attainment of the equilibrium value for the surface tension of a surfactant solution is an example. Another example is the restoration force that spontaneously occurs in the expansion of a surface of a surfactant solution, as the result of a depletion in surfactant per unit area of the surface, resulting in an increase in surface tension. This increased surface tension is restored to the original value by diffusion of surfactant from the volume phase to the surface, or, in the case of spatially limited regions of increased surface tension, also by expansion of the surfactant film of the neighboring regions. The Marangoni effect, i.e., the transportation of a liquid layer adhering to the surfactant film to the site of higher surface tension, is observed in the latter case.

For the sake of convenience, the properties of the boundary region between two phases are regarded as properties of a two-dimensional surface (see Chap. Interfacial Phenomena). Although this model representation satisfactorily explains many phenomena, it does not provide a detailed understanding of the conditions in boundary regions between two phases. For example, lamellae, membranes, or multimolecular surface films should no longer be regarded as two-dimensional; rather, they form three-dimensional structures between two phases (i.e., a third phase, known as the interphase).

4. Relationship between Structure and Properties of Surfactants

The nature of the hydrophilic group of a surfactant exerts a decisive influence on the behavior of the surfactant in aqueous solution. The solubility of ionic surfactants depends on the electrolytic dissociation and solvation of the hydrophilic group, whereas the solubility of nonionic surfactants depends essentially on the hydration of the polarized but undissociated hydrophilic group. The solubility of ionic surfactants generally increases with increasing temperature, whereas that of nonionic surfactants decreases because the extent of hydration via hydrogen bond formation decreases with increasing temperature (see Figs. 7 and 8). Aqueous anionic-surfactant gels (Fig. 7) dissolve in a monodisperse fashion at low concentration, and in a micellar manner at higher concentrations. The solution temperature rises only slightly with increasing concentration, and likewise the critical micelle concentration increases only slightly with temperature. The triple point monodisperse solution – gel – micellar solution is known as the Krafft point (or temperature), and is characteristic for each ionic surfactant. It can be determined sufficiently accurately for most purposes as the point at which a surfactant solution above the critical micelle concentration becomes clear on heating. This is because above the critical micelle concentration the solution temperature (clear point) depends only slightly on the concentration.

Figure 7. Phase diagram of an anionic surfactant of the sulfonate type in aqueous solution, as a function of concentration *c* and temperature *T*

Figure 8. Phase diagram of a nonionic surfactant of the ethoxylate type in aqueous solution, as a function of concentration *c* and temperature *T*

The phase diagram of a nonionic alkyl polyethylene glycol ether is illustrated schematically in Figure 8. The critical micelle concentration decreases with increasing temperature. At elevated temperature micellar solutions separate into two phases; thus, initially clear solutions become turbid on heating. The temperature at which a solution of a nonionic surfactant becomes turbid is termed the turbidity or cloud point, and is a characteristic parameter of a nonionic surfactant.

Ionic surfactants aggregate into micelles at molar concentrations that are a factor of ten higher than in the case of nonionic surfactants. The reason for this is the electrostatic repulsion of the surfactant ions, which counteracts orientated association. In the presence of electrolytes the electrostatic repulsion of the surfactant ions is counteracted to some extent due to the increased concentration of the counterions; electrolytes thus greatly reduce the CMC of ionic surfactants and increase the aggregation number. The CMC of nonionic surfactants is only slightly influenced by electrolytes (see Fig. 4). Critical micelle concentrations of some well-defined chemical compounds are listed in Table 1, while those of some industrial products are listed in Table 2. The tables illustrate the influence of the chemical structure of the surfactants on the CMC and the surface tension:

1. With linear alkyl groups in the hydrophobic part, the amphiphilic substances require 7 – 9 carbon atoms or more in the hydrocarbon chain to exhibit surface activity and micelles formation. Only with the very highly surface-active fluorosurfactants, whose fluorocarbon residues are extremely hydrophobic, is interfacial activity observed for shorter chains, starting with perfluorobutanecarboxylic acid and perfluorobutanesulfonic acid.
2. In a series of homologues the CMC decreases with increasing size of the hydrophobic residue. For linear alkyl hydrophobic groups, Stauff's rule applies:

   $$\log(\mathrm{CMC}) = A - Bn$$

   where *A* and *B* are constants and *n* is the number of carbon atoms in the alkyl residue. Traube's rule states that in a homologous series the interfacial activity increases with increasing size of the hydrophobic group and that the surfactant concentration at which a specific interfacial activity is achieved decreases with increasing size of the hydrophobic group. For simple linear hydrocarbon chains in the hydrophobic part

   $$\log C_n = -n \log A + B$$

   where C_n is the concentration of the homologue, *n* is the number of carbon atoms in the hydrocarbon chain, and *A* and *B* are constants. For aqueous solutions of sodium salts of fatty acids, for example, the concentration required to lower the surface tension by a specific amount is three times lower when the alkyl chain is extended by one methylene group.
3. In a series of isomers the CMC and interfacial activity increase with increasing internal position of the hydrophilic group.
4. Branching of the hydrophobic hydrocarbon has the same effect on the CMC and interfacial activity as a shortening of a linear hydrocarbon residue. A central rather than terminal substitution of the alkyl chain by a phenyl group bearing the hydrophilic group has the same effect (effective chain length — see Fig. 9).
5. For nonionic surfactants of the polyethylene glycol ether type the water solubility and CMC increase with increasing length of the polyethylene glycol chain.

Table 1. CMCs of some surfactants of defined structure, and their surface tensions at the CMC

Surfactant	Temperature, °C	CMC		Surface tension,
		mmol/L	g/L	mN/m
Na 1-decyl sulfate	50	34.0	8.3	40

Figure 9. Effective chain length of alkylbenzenesulfonates

Micelle formation, interfacial activity, and absolute values of the interfacial tension are decisively influenced by the size and structure of the hydrophobic groups, which determine the cohesive forces between the surfactant molecules and ions as well as their spatial requirement at the interface. Cohesive forces that increase with increasing chain length exist between surfactants having unbranched alkyl residues, and are stronger than the forces between branched alkyl chains. Surfactants with linear alkyl groups accordingly associate at lower concentrations than those with branched chains, while surfactants with long chains associate at lower concentrations than those with short chains.

Fluoroalkyl groups are substantially more hydrophobic than the corresponding aliphatic alkyl groups. Fluorosurfactants therefore form micelles at much lower concentrations than their aliphatic analogues.

Surfactants with straight- chain aliphatic groups can form a tightly packed film at the interface, with parallel linear chains; their spatial requirement is small, and the strength (tension) of the film increases with increasing chain length. In contrast to branched- chain surfactants, such surfactants only reduce the surface tension slightly, though they do so already at low volume concentrations. Surfactants with branched- chain hydrophobic groups, which reach the CMC only at relatively high concentrations, lead to lower surface tensions because their surface films have a relatively low cohesion but relatively high spatial requirement. Surfactants with straight- chain aliphatic groups have been referred to as “efficient” surfactants since they are already active at low concentrations, and surfactants with branched hydrophobic residues as “effective” surfactants, since they produce a marked decrease in surface tension, albeit at higher concentrations [34] (Fig. 10).

Figure 10. Surface tension γ of an efficient and an effective surfactant as a function of concentration *c*

The low cohesion between the perfluoroalkyl groups in perfluoroalkyl surfactants results in very low interfacial tensions in solution. Surfactants with methylpolysiloxanes as hydrophobic group lie between surfactants with alkyl groups, and perfluoroalkyl surfactants as regards interfacial tension, due to the moderate cohesive forces between the

dimethylsiloxane groups.

On account of the marked decrease in the interfacial and surface tension, solutions of effective surfactants generally exhibit good wetting and foaming abilities but have a low detergent power due to the high CMC; the opposite is true for efficient surfactants. This rule of thumb applies provided that the molecular masses of the surfactants are not so large that the adjustment of the equilibrium state is adversely affected by the reduced diffusion rate. Minima of the interfacial and surface tensions as a function of the length of the hydrophobic or hydrophilic (ethoxylate) residue given in the relevant literature refer to “dynamically” measured values, i.e., values that have been obtained without waiting for equilibrium to be established, which can take several hours in the case of slowly diffusing surfactants. For application technology, however, it is largely the dynamic interfacial tensions that are decisive, since in processes of wetting, washing, emulsification, etc., the instantaneous effects are of most importance.

Surfactants of varying structures form mixed films at interfaces. At low concentration surface-active substances with the higher surface activity preferentially accumulate in the interface. With increasing surfactant concentration the more strongly surface-active species may be expelled from the interface and absorbed by micelles in the volume phase, forming mixed micelles. As a result the interfacial tension, which drops with increasing surfactant concentration until the CMC is reached, may subsequently increase, reaching a constant end value (Fig. 11).

Figure 11. Surface tension γ of a contaminated surfactant as a function of concentration *c*

Such concentration-dependent interfacial tension behavior is often observed for industrial surfactants, which consist of mixtures of various chemical species. At fairly high concentrations of the second component permanent mixed films may form, whose properties deviate from the films of the individual components because of their different structure and, thus, stability. For example, lauryl alcohol in lauryl sulfate or lauric acid ethanolamide in alkylbenzene sulfonate stabilizes the foam on aqueous solutions of the corresponding surfactants because the nonionic substances are incorporated in the film and oriented in a hydrophilic – hydrophobic manner. Thus, the distance between the electrically charged hydrophilic groups of the surfactant is increased and their electrostatic repulsion is reduced.

Similar to mixed films at interfaces mixed micelles can form in solution, whose structure can be greatly altered by the mixing proportions up to the formation of “swollen” micelles, which are regarded as constituents of microemulsions.

[Top of Page]

5. Industrial Development

The industrial development of the wide range of surfactants now available received its initial and most important stimulus from the burgeoning textile industry of the mid-1800s. The various processes involved in the finishing and processing of raw cotton and wool into finished textiles required, besides the soap and natural saponins (⟶ Saponins) known from antiquity, special surface-active substances, dispersants, softeners, and sizing agents, with resistance to water hardness being one of the initial requirements. The first steps in this direction were taken by RUNGE in 1834 and by MERCER in 1846 with sulfated olive oil, followed in 1875 by turkey red oils, which were obtained by sulfating castor oil. These processes underwent many improvements, and are still of some importance.

Until 1930 industrial surfactant chemistry was almost exclusively an adjunct of the textile industry, and only in the 1930s did developments occur that opened up new markets for synthetic or semi-synthetic surfactants, including household detergents. Whereas oils and fats were formerly, with a few exceptions, the only raw materials for surfactants including soaps, during this period raw materials based on coal and petroleum also became increasingly important, although the natural materials based on oils and fats have never completely lost their importance.

In 1963 PÜSCHEL identified five periods in the development of surface-active substances [35]:

1. Up to 1925: Turkey-red oils
2. From 1925 to 1929: highly sulfonated oils
3. From 1929 to 1935: invention of the principal types of synthetic surfactants
4. From 1935 to 1945: coal and petroleum were exploited as raw material base
5. From 1945 to 1960: new, special types of surfactants were developed

This subdivision of surfactant development can be concluded by a sixth period beginning around 1960, characterized by increasing environmental awareness, which has considerable repercussions on research and technology in surfactant chemistry. Nowadays, particular attention is being paid to “mild” surfactants, i.e., those with a low irritation potential for the skin and mucous membranes.

Two developments in the 1930s in Germany have permanently affected the development of surfactant chemistry.

SCHRAUTH et al. at the Deutsche Hydrierwerke in Rodleben accomplished the catalytic high pressure hydrogenation of fatty acids to fatty alcohols. BERTSCH et al. at H. T. BÖHME in Chemnitz, who had already developed sulfated fatty acid esters (Avirol) and fatty acid amides (Humectol), obtained primary alkyl sulfates by sulfating fatty alcohols, which already appeared on the market in 1932 as a constituent of the specialty detergent FEWA, the first soap-free detergent.

In 1930, SCHÖLLER and WITTWER at I.G. Farbenindustrie in Ludwigshafen invented ethoxylation, i.e., the reaction of compounds having a dissociating hydrogen atom with ethylene oxide. This reaction leads to derivatives of poly(ethylene glycols) or also oligo(ethylene glycols), known as ethoxylates. This was the birth of a new class of surfactants, the nonionic surfactants. I.G. Farbenindustrie introduced in rapid succession the following nonionic surfactants to the market:

Fatty acid ethoxylates	Soromin SG
Fatty alcohol ethoxylates	Peregal O
Alkylphenol ethoxylates	Igepal C

Parallel to these developments, I.G. Farbenindustrie offered a range of new oleic and fatty acid derivatives:

O-acylisethionate	Igepon A
N-acyl-*N*-methyltaurine	Igepon T
N-acylsarcosine	Medialan
N-acylaminoethyl sulfate	Igepon C

The particularly dermatologically friendly condensation product formed from oleic acid and oligopeptides, Lamepon A, was developed at Chemische Fabrik Grünau.

The first cationic surfactants, *N*-acylaminoethyltrialkyl ammonium salts, Sapamines, were produced in 1927 by Ciba. In 1934 DOMAGK discovered the disinfectant action of cationic surfactants, the so- called invert soaps; I.G. Farbenindustrie developed alkyldimethylbenzyl ammonium salts under the name Zephirol. Betaines (Du Pont) and ampholytes (Th. Goldschmidt) came later, in 1937 and 1948.

In the mid-1940s Atlas Powder introduced, a new class of nonionic surfactants (Spans and Tweens) to the market with the fatty acid sorbitan esters and their ethoxylates.

The first surfactant to be based on a coal product was diisopropylnaphthalenesulfonate, which was synthesized in 1917 by GUNTHER at BASF. This compound and other short- chain dialkylnaphthalenesulfonates are still used as wetting agents under the generic name Nekal. Alkylbenzenesulfonates with longer chain alkyl groups were produced in 1933 by I.G. Farbenindustrie and, independently, in 1936 by National Aniline in the United States. The predominant position in terms of quantity that alkylbenzenesulfonates nowadays occupy was achieved, however, only after 1945. Up to then, besides soaps, alkyl sulfates and alkanesulfonates played an important role in detergents and cleansing agents. Alkyl sulfates are obtained by sulfating primary (natural) alcohols or by addition of sulfuric acid to long- chain olefins. In the latter case secondary alkyl sulfates are obtained, which were marketed as Teepol (Shell, 1934). Secondary alkanesulfonates were produced on an industrial scale from 1941 onward at I.G. Farbenindustrie in Leuna by sulfochlorination followed by saponification; they are still important nowadays as emulsifiers under the name Mersolat.

Until the expansion of refinery capacities and the conversion of chemicals production to raw materials derived from petroleum, the mainly linear hydrocarbons obtained from Fischer –Tropsch synthesis plants were used in Germany as feedstocks for the industrial production of surfactants. C_{10} – C_{14} alkenes were used for alkylating benzene to

produce alkylbenzenesulfonates, while C_{13} – C_{18} alkanes were used for the production of alkanesulfonates. The higher molecular mass hydrocarbons (Fischer – Tropsch slack wax) were oxidized to fatty acids, which were used among other things as synthetic soaps.

With the expansion of petroleum refining low molecular mass olefins became available as starting materials. Ethylene was particularly valuable as a starting material for ethylene oxide, the basic building block of nonionic surfactants, and propylene as the starting material for hydrophobic groups. Propylene trimer was used for producing isononylphenol, the starting material for nonionic surfactants, while propylene tetramer was used for producing branched- chain dodecylbenzene, the starting material for a new type of alkylbenzene sulfonates (tetrapropylbenzenesulfonate), which was primarily developed in the United States and was also widely used in Europe.

In the 1950s the alkylbenzenesulfonates, nonylphenol ethoxylates, and fatty alcohol ethoxylates were produced in such amounts that a very large proportion of surfactant demand could be met. Nevertheless, the development of special surfactants for particular purposes continued after 1950. During this period novel surfactants were synthesized, in particular by incorporating new hydrophobic groups into the surfactant molecules. Examples include the Pluronic and Tetronic types produced by Wyandotte, in which polypropylene glycol or polyoxypropylated ethylenediamine are used as hydrophobic building blocks, and also the fluorosurfactants introduced from 1950 onward by 3 M containing (per)fluoroalkyl groups, and the silicone surfactants produced by TH. GOLDSCHMIDT, containing a large variety of polydialkylsiloxanes as hydrophobic groups.

Although for a long time surfactant chemistry obtained a basic stimulus from the textile industry, nowadays the development of industrial products is largely determined by the requirements of the detergent, cleansing agent, and cosmetics industries since the bulk of surfactants is nowadays used in these sectors.

From 1960 onward the demand for biodegradability of surfactants in detergents and cleansing agents led to major changes. The most important product, tetrapropylenebenzenesulfonate, was replaced with great technical effort and expenditure by linear alkylbenzenesulfonate; in addition to nonylphenol ethoxylate, fatty alcohol ethoxylates based not only on natural raw materials but also on synthetic products appeared. A further ecological factor — the demand for a reduction or elimination of phosphate in detergents — together with the demand for a more rapid biodegradability, stimulated new technical developments: alkanesulfonates, alkenesulfonates, and α-sulfo fatty acid esters were considered as potential industrial products. Alkanesulfonates, produced by sulfoxidation of paraffins in a process developed in the 1940s by Hoechst, have in the meantime secured a firm market in Europe. The alkenesulfonates have achieved some importance in the United States and Japan, whereas the α-sulfo fatty acid esters have still not found any major use. With the expansion of oil palm plantations (e.g., in Malaysia and the Philippines), fatty alcohol sulfates based on these renewable raw materials are becoming increasingly important.

With the demand for particularly mild surfactants, besides the fatty alcohol ether sulfates and sulfosuccinic acid esters of fatty alcohol oligoglycol esters, a number of surfactants that were already developed in the 1930s have attracted renewed interest, including fatty acylisethionates and fatty acyltaurates, amino acid derivatives, ampholytes and betaines, carboxymethylated fatty alcohol ethoxylates, and so- called sugar surfactants. In parallel to the demand for mild products, there has been a more emotionally motivated wish for “natural” products, raw materials and surfactants based on renewable, preferably plant raw materials. There is thus a potential for substituting products from petrochemical raw materials by those from renewable raw materials, which will be reflected in the extent to which corresponding amounts of renewable raw materials, primarily coconut, palm, and palm kernel oils, are available at comparable prices for industrial purposes [36].

[Top of Page]

6. Anionic Surfactants

6.1. Carboxylates

Soaps, the salts of fatty acids, are still important among surfactants (⟶ Soaps). Soaps are obtained mainly by saponification of natural fats. The oxidation of paraffins, olefins, aldehydes, or alcohols (Stass reaction) is no longer of importance for the production of fatty acids. The salts of carboxylic acids occurring in petroleum (naphthenic acids), which are also surfactants, are treated in ⟶ Metallic Soaps.

6.1.1. *Carboxymethylated Ethoxylates*

The sensitivity of soaps to water hardness is a disadvantage for some applications (e.g., textile washing). In contrast, the so-called super soaps, the sodium salts of carboxymethylated ethoxylates exhibit an extreme hardness resistance combined with good water solubility.

The carboxymethylated ethoxylates or polyether carboxylates, as they have also been named, are known to be dermatologically friendly. Since they also have outstanding dispersion and emulsification properties, they are suitable for a wide range of uses, for example as surfactants in detergents and cosmetics [37], [38], and as industrial emulsifiers [39].

The carboxymethylated ethoxylates are prepared by reacting an alcohol ethoxylate or alkylphenol ethoxylate with chloroacetic acid and caustic soda:

$$\mathrm{R-O-[CH_2CH_2O]_n-H + ClCH_2COOH + 2\,NaOH}$$
$$\downarrow$$
$$\mathrm{R-O-[CH_2CH_2O]_n-CH_2COONa + NaCl + 2\,H_2O}$$

The sodium chloride byproduct is best removed by acidifying the reaction mixture, whereby the carboxylate separates as water-insoluble polyethercarboxylic acid and the sodium chloride remains in the aqueous phase. The polyether acids are clear, mobile liquids that can be transported in stainless steel or plastic containers, they are the most suitable form for handling this group of products. By neutralizing them with caustic soda colorless, highly viscous pastes are obtained that yield mobile solutions only at concentrations below 25 wt %. Typical data for some carboxymethylated products are listed in Table 3.

6.1.2. *Amino Acid Derivatives*

Condensation products of fatty (oil) acids and amino acids are also less sensitive to hardness and hydrolysis than soaps. Sarcosides, for example, are obtained by reacting a fatty acid chloride with sodium sarcosinate according to the Schotten-Baumann reaction:

$$\mathrm{RCOCl + CH_3NHCH_2COONa + NaOH \rightarrow RCON(CH_3)CH_2COONa + NaCl + H_2O}$$

Sarcosides are good wetting agents and lime soap dispersants.

Industrially more important than the condensation products of amino acids are those with oligopeptides, which are obtained by partial hydrolysis of collagen, an animal skeletal

protein that has no antigenic properties. The oligopeptides have molecular masses of 200 – 600. The condensation products are prepared similarly to the sarcosides, by condensation of a fatty acid derivative (chloride or anhydride) at the terminal amino group of the oligopeptide [40], [41].

The products can be freed from byproducts by acidifying the reaction mixture; the pure condensation products separate as acids, which can be redissolved with a base.

As salts, fatty acid/protein condensation products are highly water soluble. They have a high lime soap dispersion power and foaming ability. Fatty acid/protein condensation products are preferentially used as highly skin-friendly surfactants in cosmetic preparations, bodycare agents, shampoos, and children's bathing products. They are stored and transported as 30 – 40 % solutions in steel or plastic vessels. If preserved against bacterial growth, they can be stored for prolonged periods at 20 °C and above. Typical data of two commercial products are listed in Table 4.

CAS Numbers. Sodium lauroyl sarcosinate [137-16-6], potassium cocoyl hydrolyzed collagen [68920-65-0], triethanolamine cocoyl hydrolyzed collagen [68952-16-9], potassium undecenoyl hydrolyzed collagen [68951-92-8], triethanolamine abietoyl hydrolyzed collagen [68918-77-4].

Producers. Sarcosides are produced by Croda, Hoechst, and ICI in Europe; Clough, Grace, and Stepan in the United States; Nikko Chemicals in Japan; and Zohar in Israel.

Fatty acid/protein condensation products are produced by Croda and Henkel in Europe; Ajinomoto, Croda, Henkel, and Inolex in the United States; and Ajinomoto and Nikko Chemicals in Japan.

6.2. Sulfonates

Sulfonates are the salts of sulfonic acids, in which a hydroxysulfonyl group is bonded via the sulfur atom directly to a carbon atom of the hydrophobic residue. This bond is thermally and chemically very stable. The strong affinity of the sulfonate group for water results in good water solubility, which decreases with increasing molecular mass. The alkaline-earth salts of sulfonic acids are less soluble in water than the alkali metal salts. The sensitivity of sulfonates to water hardness increases with increasing molecular mass. Being salts of strong acids, the alkali and alkaline-earth sulfonates give a neutral reaction in aqueous solution.

Sulfonates are nowadays the most important group among the synthetic surfactants. Besides the sulfonates discussed hereinafter, lignin sulfonates (⟶ Lignin – Commercial Lignins) and petroleum sulfonates are industrially important. Being outstanding dispersants, lignin sulfonates are used to improve the viscosity of concrete mixtures and drilling muds, while petroleum sulfonates are used mainly as oil-soluble surfactants for producing water-in-oil emulsions. Both types of sulfonates could become important as surfactants in tertiary crude oil production.

6.2.1. *Alkylbenzenesulfonates [42], [43]*

p-Alkylbenzenesulfonates having (on average) 8 – 20 carbon atoms in the alkyl chain have a wide range of uses. *p*-Alkylbenzenesulfonates with less than 6 carbon atoms in the alkyl group are not surface-active.

The alkylbenzenesulfonates are mainly used in the form of sodium salts, and occasionally also as potassium and ammonium salts and as salts with aliphatic amines. The octyl- to decylbenzenesulfonates have a good wetting action, but are unsuitable as emulsifiers and cleansing agents due to the shortness of the hydrophobic group. The most universally usable alkylbenzenesulfonates are those with an average of ca. 12 carbon atoms in the alkyl chain, comprising homologues with 10 – 14 carbon atoms (dodecylbenzenesulfonate). Because of their outstanding suitability as surfactants in detergents and cleansing agents (⟶ Laundry Detergents) and their low production costs compared to other surfactants, the dodecylbenzenesulfonates are nowadays the most important group of synthetic surfactants in terms of quantity. They are a constituent of powder and liquid heavy-duty household and industrial detergents. They are used less in fine detergents, shampoos, and cosmetic preparations.

Alkylbenzenesulfonates with ≥ 15 carbon atoms in the alkyl chain are sparingly soluble in water, but are readily soluble in organic media. Solutions in mineral oils play a role as drilling and cutting oils in the metal-processing industry, and as spinning, dust-binding, and batch oils in the textile industry.

Alkylbenzenesulfonates are produced by alkylation of benzene (Friedel – Crafts reaction), sulfonation of the alkylbenzene obtained, and neutralization. In the dodecylbenzenesulfonates a distinction is made between those derived from highly branched tetrapropylene (TPS = tetrapropylenebenzenesulfonate) and those with linear alkyl groups (LAS = linear alkylbenzenesulfonate). Tetrapropylenebenzenesulfonate is less soluble in water than linear dodecylbenzenesulfonate (ca. 10 % and 20 % at 20 °C), is less toxic to fish, but is a stronger skin irritant than the latter. Sodium tetrapropylenebenzenesulfonate is less hygroscopic and less plastic than linear sodium dodecylbenzenesulfonate, and accordingly can be processed more easily into powder formulations. Tetrapropylenebenzenesulfonate is, however, becoming increasingly less important because of its unsatisfactory biodegradability.

In the first stage of the alkylbenzenesulfonate synthesis, benzene is alkylated with the corresponding alkyl chlorides or olefins. Linear alkyl chlorides are obtained by chlorination of alkanes, whereby conversion is limited to at most 30 % to minimize the proportions of polychlorinated hydrocarbons. Tetrapropylene, which can be obtained by oligomerization of propylene, is already present as an olefin. Linear olefins are nowadays obtained by oligomerization of ethylene or by catalytic dehydrogenation of linear paraffin cuts.

The oligomerization of ethylene using aluminum alkyls (Alfen process) or by transition metal complexes (Shell Higher Olefin Process, SHOP) affords mixtures of homologous, even-numbered, unbranched α-olefins with a broad Schulz – Flory molecular mass distribution [44], [45] (see also ⟶ Hydrocarbons – Oligomerization of Lower Olefins). Such olefins are less suitable for producing commercial alkylbenzene mixtures, since narrow olefin cuts are required for this purpose. One possible way of narrowing the homologue distribution is to isomerize α-olefins to olefins with double bonds, as carried out in the SHOP process, followed by comproportionation or cometathesis of higher and lower olefins. Although mixtures of olefins with internal double bonds and a broad molecular mass distribution are again formed, the advantage of this process is that the desired olefin cut (e.g., C_{10} – C_{13}) can be distilled from the mixture, and the unrequired fractions can be returned to the cometathesis reaction, so that ultimately the mixture of α-olefins with a broad distribution that is obtained in the oligomerization is converted to a mixture of linear olefins of narrow distribution having internal double bonds.

The process most widely employed nowadays for producing olefins for industrial alkylbenzene synthesis is the dehydrogenation of *n*-alkanes. In conjunction with the back-integrated process for obtaining linear starting alkane from corresponding petroleum fractions (kerosene) by means of molecular sieves and the forward-integrated benzene alkylation catalyzed by hydrogen fluoride, it is nowadays carried out worldwide in numerous plants and is known as the UOP process (Universal Oil Products) [46], [47].

Nowadays, exclusively aluminum chloride and hydrogen fluoride are used as alkylation catalysts in alkylbenzene synthesis, whereby hydrogen fluoride can only be used for alkylation with olefins but not with alkyl chlorides.

A fixed-bed catalyst was described for the first time in 1990, which has advantages compared to hydrogen fluoride- catalyzed alkylation and is to be marketed by UOP under the name “Detal” [47], [48].

Alkylation always gives mixtures of isomeric (and homologous) alkylbenzenes. The isomer distribution of the alkylbenzenes obtained with the two catalysts is different. Both processes are Friedel – Crafts reactions, in which only secondary or tertiary alkyl residues occur on the benzene ring. Regardless of whether primary or secondary linear alkyl chlorides or linear olefins having terminal or internal double bonds are used as starting materials, alkylbenzenes are always obtained in which the phenyl groups is bonded internally along the alkane, but not in the terminal position.

The isomer distribution depends on the catalyst used. With aluminum chloride and linear alkyl chlorides or olefins roughly the same isomer distribution is obtained, in which 2-phenylalkanes predominate and 3-, 4-, and 5-phenylalkanes, etc., are present in lesser amounts. If benzene is alkylated in the presence of hydrogen fluoride, then 2-phenylalkanes are present in the lowest concentration in the resultant isomer mixture, and the proportion of the more internal phenylalkanes increases the closer the position of the phenyl group to the middle of the alkane chain. These relations are illustrated in Table 5 for industrial alkylbenzenes. Various isomerization reactions are responsible for these isomer distributions. Lewis acids such as aluminum chloride isomerize the phenylalkanes already formed, whereas protic acids such as hydrogen fluoride isomerize the unreacted olefins but not the phenylalkanes [49]. If branched olefins such as tetrapropylene are used as starting material, the phenyl residue is always bonded to a tertiary carbon atom, e.g.:

Table 5. Composition of industrial alkylbenzenes in wt % [50]

Component	From olefin with HF catalysis (molar mass 240)	From alkyl chloride with $AlCl_3$ catalysis (molar mass 241)	From olefin with $AlCl_3$ catalysis (molar mass 240)

5-Phenyldodecane	24	18	18
6-Phenyldodecane	25	18	17

Processes for preparing linear industrial “dodecylbenzene”, a mixture of decylbenzene to tridecylbenzene, from linear alkyl chlorides and from linear olefins are described hereinafter by way of example, the preparation of the alkyl chlorides or olefins being integrated components of the processes.

Alkylation with Alkyl Chlorides (Fig. 12). The alkane, a homologous mixture of linear alkanes with average carbon number 12, is reacted with gaseous chlorine at 100 – 140 °C in a chlorination tower to a conversion of 30 mol %. To minimize backmixing and, thus, the proportion of higher chlorinated paraffins, the chlorination can also be carried out in a cascade of reactors. Suitable reactor materials are lead, silver, or enamel; iron is not suitable.

Figure 12. Preparation of a linear alkylbenzene by the aluminum chloride process

The hydrogen chloride released in the reaction $RH + Cl_2 \longrightarrow RCl + HCl$ escapes from the head of the chlorination tower and is washed in countercurrent with fresh alkane to trap unreacted chlorine. The hydrogen chloride is of high purity and can be used for further chemical syntheses. The “chlorine oil”, consisting of alkyl chlorides and unreacted paraffin, is passed to the alkylation stage. The alkyl chlorides consist of positional isomers, secondary alkyl chlorides predominating by far.

The active catalyst in the alkylation is a liquid complex compound formed in the reaction mixture and containing up to 35 wt % aluminum chloride. This complex is only slightly soluble in the reaction mixture and can, therefore, be separated as a heavier phase and recycled. Losses can be replenished by adding fresh aluminum chloride or aluminum, which reacts with hydrogen chloride to form aluminum chloride.

The alkylation is preferentially carried out in glass-lined reaction towers at 80 °C. To minimize multiple alkylation, benzene is added in a manyfold molar excess. The hydrogen chloride released in a stoichiometric amount according to the equation $RCl + C_6H_6 \longrightarrow RC_6H_5 + HCl$ maintains the reaction mixture in a turbulent state and is removed at the upper end of the reactor. It is also washed with fresh paraffin, but still contains low boiling point hydrocarbons (e.g., isobutane) and accordingly cannot be reused directly.

The reaction mixture leaving the alkylation tower is passed to a separating vessel in which the catalyst complex separates out. The organic phase is freed from residual catalyst by washing with water and sodium hydroxide and is worked up in a distillation unit. First benzene, then unreacted paraffin, and finally alkylbenzene accounts for only ca. 10 % of the alkylation mixture are separated. More highly alkylated benzenes and diphenylalkanes formed by reaction with dichloroalkanes in the “chlorine oil” can be isolated as a tail fraction.

The dichloroalkanes react also form bicyclic compounds such as 1,3-dialkyltetralins, which during distillation remain in the alkylbenzene in amounts of 5 – 10 wt %

Alkylation with Olefins. The UOP process for producing alkylbenzenes, the most widely used process worldwide, is illustrated in Figure 13 [47]. The process consists of three stages: olefin production (Pacol = paraffin conversion to olefins), selective hydrogenation (DeFine), and alkylation.

Figure 13. Preparation of a linear alkylbenzene by the UOP process

a) Heater; b) Heat exchanger; c) Dehydrogenation reactor; d) Gas – Liquid separator; e) Hydrogenation reactor; f) Stripper column; g) Alkylation reactor; h) Acid settler; i) HF stripper; j) Benzene column; k) Paraffin column; l) Rerun column

The dehydrogenation of *n*-alkanes takes place at ca. 500 °C and with a slight hydrogen excess pressure of ca. 3 bar over a fixed-bed of modified platinum catalyst on aluminum oxide.

The alkane conversion is held at 10 – 15 % to minimize further dehydrogenation to diolefins and aromatics. The hydrogen released contains small amounts of lower alkanes; some of the hydrogen is recycled to the dehydrogenation reactor, while another part is used in a connected reactor for the selective hydrogenation of diolefins, formed in small

amounts, to monoolefins (DeFine). The removal of diolefins is important to suppress the formation of byproducts,bicyclic hydrocarbons, and diphenylalkanes in the alkylation. The dehydrogenation product, containing 10 – 15 wt % monoolefins is passed to the alkylation reactor, in which it is intensively mixed with benzene and hydrofluoric acid, which is only slightly miscible with the hydrocarbons. The benzene is used in a manyfold molar excess to minimize multiple alkylation. The reaction is carried out at < 50 °C with intensive cooling. The acid catalyst is removed in a separating vessel connected to the reactor and is recycled to the alkylation reaction; a partial stream is passed through a distillation column (not shown in Fig. 13) in which the hydrofluoric acid (*bp* 19 °C) is freed from small amounts of dissolved, higher-boiling organic constituents, the so- called acid tar, a constant regeneration of the catalyst thereby being ensured. Since water is excluded from the whole alkylation section the latter can be manufactured from normal steel without risk of corrosion.

After stripping residual dissolved hydrogen fluoride in a distillation unit, the upper, organic phase from the separating vessel is fractionated into benzene, alkane, alkylbenzene, and higher-boiling compounds, the so- called heavy alkylate, which can be further fractionated. Benzene and alkane are returned to the process.

The distillation is simplified if paraffin-free olefins (e.g., tetrapropylene or linear alkenes from the SHOP process) are used for the alkylation. In the preparation of higher alkylbenzenes such as hexadecylbenzene, paraffin-free olefins are preferably used as starting materials since the distillation becomes more difficult as the boiling point rises.

Formerly, hydrofluoric acid was the exclusive catalyst for the alkylation of benzene with olefins; however, more recently a plant came on stream in which aluminum chloride is also used for this reaction [50]. The linear alkylbenzene produced in this way is reported to be particularly pure.

Sulfonation. The sulfonation of alkylbenzenes, which at low temperature mainly occurs in the *p*-position, can be performed with concentrated sulfuric acid, oleum, or sulfur trioxide. Sulfonation with sulfur trioxide is now the predominant process. It has major advantages over sulfonation with sulfuric acid or oleum, including much faster reaction rate and higher space – time yield. Also, in sulfonation with sulfur trioxide no waste sulfuric acid is formed, and accordingly there are no workup or disposal problems.

The high reaction rate, combined with strong evolution of heat (ca. 170 kJ/mol, corresponding to ca. 700 kJ/kg of dodecylbenzene), necessitates intensive mixing and efficient cooling. The sulfur trioxide used is diluted to 4 – 8 % in air or nitrogen as carrier gas. This mixture is formed in sulfur combustion combined with the contact process; it can also be obtained by passing air or nitrogen over heated oleum or liquid sulfur trioxide.

Bubble- column reactors are suitable for discontinuous sulfonation with sulfur trioxide. The mechanical momentum of the inert gas produces a high turbulence, which can be enhanced by stirrers. The heat of reaction is dissipated through the jacket, through internal cooling tubes and, in the case of rapid product circulation, by external heat exchangers. The inert gas leaving the reactor must be freed of entrained sulfur trioxide and acid droplets by washing with alkylbenzene, for example. The course of the reaction is followed by acidimetric titration, and the addition of sulfur trioxide is discontinued when the desired “titer value” is reached.

The preferentially employed continuous sulfonation with sulfur trioxide is carried out in special reactors in which backmixing of the reaction material is largely avoided and in which the reaction takes place in intensively cooled thin layers. Many modifications of suitable reactors, namely falling film, multitube, or concentric tube reactors, are available [51], [52]. Such reactors are used particularly for the sulfonation of alkenes and for sulfation of ethoxylates, since with these substrates localized overheating and excessive concentrations of sulfur trioxide can have an even more disadvantageous effect on the product quality than in the case of alkylbenzenes.

The production of alkylbenzenesulfonate is illustrated in Figure 14. The sulfur trioxide/inert gas (air or nitrogen) mixture passes via a mist eliminator, in which entrained sulfuric acid is removed, to the continuous sulfonation reactor. The sulfur trioxide is used in a slight excess (up to 10 mol %).

Figure 14. Continuous production of alkylbenzenesulfonate

a) Mist separator; b) Sulfonation reactor; c) Gas separator; d) Digestor; e) Hydrolyzer; f) Mixing pump; g) Intermediate vessel

The residence time of the liquid and gas in this reactor is a few minutes, and the reaction temperature is 40 – 50 °C. The reaction product passes to a separator, where the inert gas is removed. This waste gas is washed with liquid (e.g., alkylbenzene) to remove entrained acid droplets. The degassed sulfonation mixture passes through a digester where small amounts of pyrosulfonic acid present react with unreacted alkylbenzene:

Acid anhydride, also present in small amounts, is hydrolyzed at 80 °C in a following hydrolyzer by adding 1 – 2 wt % of water:

The sulfonic acid obtained in this way can then be neutralized directly, but as with sulfonic acid produced batchwise it can also be transported to the consumption site and neutralized there.

Anhydrous alkylbenzenesulfonic acids do not attack iron if water (and also atmospheric moisture) are excluded. Dodecylbenzenesulfonic acid can therefore be stored and dispatched in steel vessels. It can easily be poured, transferred, and metered as a liquid. Typical characteristic data of a high-quality dodecylbenzenesulfonic acid are given below:

Content of alkylbenzenesulfonic acid	97 – 98 %
Content of sulfuric acid	ca. 0.5 %
Content of water	0 %
Content of unsulfonated compounds	1.5 – 2 %
Titer value (mL 1 N NaOH/10 g acid)	31 – 32 mL
g Sodium salt/100 g acid	103 – 105 g
Density at 50 °C	ca. 1.03 g/mL
Viscosity at 50 °C	ca. 300 mPa · s
Color	yellow to brown

Neutralization. In the neutralization of the alkylbenzenesulfonic acid, in general only so much water is added as is necessary to form a flowable 50 % paste. The heat of neutralization is ca. 180 kJ/kg; a temperature of 60 °C is maintained by cooling. During neutralization the reaction mixture must be intensively mixed to avoid locally excessive sulfonic acid concentrations, since sulfonic acid containing 10 – 50 % water forms highly viscous gels. It has proved most convenient to add acid and sodium hydroxide continuously, while monitoring the pH, to an already neutralized mixture. In the continuous process illustrated in Figure 14 this is effected by circulating a large stream of already neutralized product and adding sulfonic acid as well as sodium hydroxide to this product stream, just in front of the mixing pump.

The brown to dark brown sulfonic acid becomes considerably lighter in color during neutralization. The light brown sulfonates obtained can be lightened by adding 1 – 3 wt % of sodium hypochlorite solution (containing 100 – 150 g of active chlorine per liter). The product then contains small amounts of chloride ions, which can cause stress corrosion cracking in steel, especially at high temperature. The apparatus for the bleaching stage must therefore be cladded with tantalum, silver, hastelloy, or earthenware.

Storage and Dispatch. Linear alkylbenzenesulfonates are water-soluble at 20 °C in an amount of up to 25 wt % to form clear solutions, and at higher concentrations pastes are formed that in the concentration range from 30 % to 60 % separate into two phases after a few hours. Such pastes must therefore be stirred during storage. The 75 % pastes do not decompose into two phases. The 65 – 75 % pastes can be dispatched only in the hot state on account of their high viscosity, and at room temperature they solidify to form rigid gels. The pastes, which can readily be pumped at 60 – 80 °C, can be stored and transported in stainless steel or glass fiber reinforced polyester vessels. They can be conveyed through heated stainless steel pipelines by using rotary piston pumps.

Anhydrous alkylbenzenesulfonates are hygroscopic and tend to agglomerate due to absorption of atmospheric moisture. Additives such as sodium sulfate or sodium toluenesulfonate counteract agglomeration; alkylbenzenesulfonates containing such additives can be worked up directly into pulverulent formulations. Anhydrous alkylbenzene

sulfonate is obtained by drying hydrated pastes, e.g., on a drum dryer; it can be packed in plastic bags and palleted. Some typical data of an industrial sodium alkylbenzene sulfonate in various concentrations are shown in Table 6.

Table 6. Typical characteristic data of an industrial sodium alkylbenzenesulfonate

Property	Concentration			
	50 %	**75 %**	**80 %**	**90 %**
Appearance at 20 °C	yellowish, flowing, inhomogeneous paste	yellowish, viscous, homogeneous paste	white to yellowish powder	white to yellowish powder
Active substance, wt %	50	75	80	90

Sodium chloride, max. wt %	0.3	0.3	0.5	0.5
Neutral oil, max. wt %	1	1	1	1
Iron, max. ppm	5.0	5.0		
Sodium toluenesulfonate, wt %			14	
Water, wt %	remainder	remainder	1	1.5
Iodine color value (10 % solution)	1	1.5		
pH (2 % in fully deionized water)	7.5 – 8.5	7.5 – 8.5	8	8 – 9
Density, g/mL	1.06	1.06		
Bulk density, g/L			470	550

CAS Numbers. C_{10} – C_{13} alkylbenzenesulfonic acid [85536-14-7], its sodium salt [68411-30-3], its diethanolamine salt [84989-15-1], its triethanolamine salt [68411-31-4]; C_{10} – C_{16} alkylbenzenesulfonic acid [68584-22-5], its sodium salt [68081-81-2], its potassium salt [68584-27-0], its ammonium salt [68910-31-6], its calcium salt [68584-23-6], its magnesium salt [68584-26-9].

Producers. Major producers of alkylbenzenesulfonic acids and alkylbenzenesulfonates in Europe include Albright & Wilson, Berol-Nobel, Harcros-Chemicals, Hüls, ICI, Kao, Manro, Pulcra, Rhône-Poulenc, Stepan, Unger, Wibarco, Witco; in the United States, A. Harrison, Ardmore, Cromton & Knowles, Eastern Color & Chemical, Emkay Chemical, Exxon, Harcros, Henkel, ICI America, Pilot Chemicals, Rhône-Poulenc Surfactants, Stepan, Unger, Witco; in Taiwan, Taiwan Surfactant; and in Israel, Zohar.

Whereas the sulfonation of alkylbenzene and the neutralization of the sulfonic acid takes place in relatively simple plants and is accordingly even carried out by many producers for captive use (e.g., for detergents), production of the alkylbenzene is more complex. The number of producers of alkylbenzene is therefore limited. Producers of linear alkylbenzenes by hydrogen fluoride catalysis include Hüls, Enichem, and Petresa in Europa; Vista and Monsanto in North America; YPF La Plata and Deten in South America; Al Astra in Saudi Arabia; Egyptian Generalpet in Egypt; Mitsubishi Petrochemical and Nippon Petroleum in Japan; Isu Chemical in South Korea; and Formosan Union in Taiwan. Enichem and Wibarco in Europe, Vista in the United States, and Nalken in Japan also produce alkylbenzene using aluminum chloride as catalyst.

Producers of tetrapropylenebenzene include Chevron in France, Monsanto in North America, Pemex in Mexico, Mitsubishi Petrochemical and Nippon Petroleum in Japan, and Formosan Union in Taiwan.

6.2.2. *Alkylnaphthalenesulfonates*

The first synthetic surfactants based on fossil raw materials were the alkylnaphthalenesulfonates such as dipropylnaphthalene- and dibutylnaphthalenesulfonates, which still play a role as wetting agents in the textile industry. These substances are obtained in a one-pot reaction by alkylating naphthalene with isopropanol, butanol, or other alcohols in the presence of concentrated sulfuric acid as catalyst and water binder, and immediately treating the reaction product with oleum to form (di)-alkylnaphthalenesulfonic acid, in a similar manner to the sulfonation of alkylbenzene, and then separating the “waste sulfuric acid”, and finally neutralizing with sodium hydroxide.

The salts of naphthalenesulfonic acid condensed with formaldehyde are chemically related to the alkylnaphthalenesulfonates, and can also be obtained in a one-pot reaction. For this purpose naphthalene is first of all sulfonated and the acid sulfonation mixture is then reacted with formaldehyde.

After the condensation the reaction product is neutralized. The molar ratio is chosen so that *n* is between 2 and 3. The salts of these condensation products are outstanding dispersants for finely divided solids, and are used as pigment dispersants and cement plasticizers.

Producers of both types of products include BASF, Hoechst, Auschem, Rhône-Poulenc, and ICI in Europe; American Cyanamid, Du Pont, Emkay, Henkel, and Witco in the United States; Takemoto Oil & Fat in Japan; and Taiwan Surfactant in Taiwan.

6.2.3. *Alkanesulfonates [53-56]*

Of the large number of possible ways of synthesizing alkanesulfonates (⟶ Sulfonic Acids, Aliphatic), only sulfochlorination (the reaction of alkanes with sulfur dioxide and chlorine to form alkane sulfonyl chlorides and their saponification with sodium hydroxide) and sulfoxidation (the reaction of alkanes with sulfur dioxide and oxygen and neutralization of the sulfonic acids) are of industrial importance. The radical addition of sodium hydrogensulfite, which proceeds with satisfactory yields only in the case of terminal olefins, gives terminal alkanesulfonates, which are only slightly soluble in water and are therefore of no industrial importance [57].

In sulfochlorination and sulfoxidation, mixtures of straight- chain alkanes with 12 to 18, preferably 13 to 17 carbon atoms, are used as starting materials. Both reactions proceed appropriate by a radical- chain mechanism. In sulfoxidation a sulfoperoxy acid first of all being formed:

$$\begin{array}{lcl} R^{\bullet} + SO_2 & \longrightarrow & RSO_2^{\bullet} \\ RSO_2^{\bullet} + Cl_2 & \longrightarrow & RSO_2Cl + Cl^{\bullet} \\ Cl^{\bullet} + RH & \longrightarrow & R^{\bullet} + HCl \\ \hline RH + SO_2 + Cl_2 & \longrightarrow & RSO_2Cl + HCl \end{array}$$

$$\begin{array}{lcl} R^{\bullet} + SO_2 & \longrightarrow & RSO_2^{\bullet} \\ RSO_2^{\bullet} + O_2 & \longrightarrow & RSO_2O_2^{\bullet} \\ RSO_2O_2^{\bullet} + RH & \longrightarrow & R^{\bullet} + RSO_2O_2H \\ \hline RH + SO_2 + O_2 & \longrightarrow & RSO_2O_2H \end{array}$$

The reaction can be started by radical initiators (e.g., peroxides) or by irradiation. Ultraviolet ra-diation is used industrially. In sulfochlorination chlorine radicals are formed initially and react with an alkane:

$$RH + Cl^{\bullet} \rightarrow R^{\bullet} + HCl$$

In sulfoxidation the mechanism of the UV initiation has not been fully clarified. It is assumed that activated sulfur dioxide is formed, which reacts with the alkane:

$$RH + SO_2^{\bullet} \rightarrow R^{\bullet} + HSO_2^{\bullet}$$

Aromatics, olefins, branched alkanes, and many other substances (e.g., amines) inhibit the radical- chain reaction; the paraffins must therefore be of high purity and linearity for both processes. With high-purity alkanes quantum yields of 10 000 Einstein are achieved in sulfochlorination; termination reactions necessitate constant re-initiation (irradiation). In sulfoxidation, alkanesulfoperoxyacids are formed initially but are unstable under the reaction conditions, and decompose with the formation of additional radicals:

$$RSO_2O_2H \rightarrow RSO_3^{\bullet} + {}^{\bullet}OH$$

$$RSO_3^{\bullet} + RH \rightarrow RSO_3H + R\cdot$$

$${}^{\bullet}OH + RH \rightarrow H_2O + R^{\bullet}$$

These radicals compensate the deficit of radicals due to chain termination; being a radical- chain reaction with degenerative branching, in pure alkanes sulfoxidation accordingly takes place after a single initiation, without further radical-producing measures. The decomposition products of the peroxyacid result in a number of byproducts (esters, alcohols, discoloring substances), which adversely affect the product quality. Sulfoxidation is therefore carried out industrially with the addition of water, which together with the sulfur dioxide present in the reaction medium traps the sulfoperoxy acid before its radical-type decomposition begins:

$$RSO_2O_2H + SO_2 \rightarrow RSO_3H + H_2SO_4$$

A radical donor is lacking if the decomposition of the peroxyacid occurs by an ionic mechanism, and sulfoxidation in the presence of water therefore requires constant initiation; in the case of pure alkanes the quantum yield is ca. 10 Einstein.

In both processes substitution mainly takes place at the internal, secondary carbon atoms of the alkane. The oxysulfonyl groups are distributed randomly over the molecule. The degree of polysubstitution increases with increasing conversion. Since the interfacial activity of the sulfonates obtained after saponification decreases with increasing proportions of polysulfonates, the paraffin conversion is restricted.

Alkanesulfonates below C_8 are not surface active. C_{12} – C_{18} sodium alkanesulfonates are readily soluble in water; the solubility is increased still further by the disulfonate fraction that is always present in industrial products. On account of their proportion of species with central sulfonate groups (“effective surfactants”) the alkane sulfonates are good wetting agents. They are preferably used in liquid formulations for detergents and cleansing agents, but can also be incorporated in washing powders. Alkanesulfonates are widely used as emulsifiers, for example, in the polymerization of vinyl chloride.

Sulfochlorination Processes. Alkanesulfonates obtained from sulfochlorination processes are known as Mersolates. They are obtained in two steps:

$$RH + SO_2 + Cl_2 \rightarrow RSO_2Cl + HCl$$

$$RSO_2Cl + 2\,NaOH \rightarrow RSO_3Na + NaCl$$

In the first stage the liquid paraffin is reacted at 20 – 40 °C in chlorine- and acid-resistant reactors (earthenware, enamel, PVC) with an approximately equimolar mixture of sulfur dioxide and chlorine under irradiation from mercury vapor lamps. The waste gas consists of hydrogen chloride contaminated with sulfur dioxide; the former can be recovered as aqueous hydrochloric acid.

The paraffin conversion is adjusted to ca. 30 %; the sulfonyl chlorides then contained in the reaction mixture (Mersol 30) in amounts of ca. 30 % consist of 94 % monosulfochlorides and 6 % disulfochlorides. Mersol H, with 45 % sulfonyl chlorides in the reaction mixture already contains 16 % disulfonyl chlorides and polysulfonyl chlorides, while Mersol D, with 80 % sulfochlorides, contains ca. 40 % disulfonyl chlorides and polysulfonyl chlorides.

In the second step the degassed sulfochlorination mixture is saponified with 10 % sodium hydroxide. Elevated temperatures must be avoided since the alkane sulfonyl chloride is desulfonated to the alkyl chloride starting above ca. 80 °C, with elimination of sulfur dioxide. While hot, the neutralized product deposits part of the unreacted alkane as upper phase, and when cold deposits most of the sodium chloride derived from the saponification as an aqueous lower phase. The remaining sulfonate “glue” is freed from residual alkane in an evaporator, which together with the paraffin from the phase separation is returned to the sulfochlorination. The sulfonate is obtained as a melt flowing at 150 – 175 °C, which solidifies on cooling drums and can be removed as flakes. The flakes are hygroscopic and readily agglutinate — they can be dispersed in water and processed into pastes. The melt can, however, also be taken up directly under pressure in water. Table 7 summarizes typical data for industrial commercial products of different concentrations.

Table 7. Typical data of industrial sodium alkanesulfonates [68037-49-01] obtained by the sulfochlorination process

	Concentration		
	32 %	**62 %**	**93 %**
Appearance	solution	paste (pumpable)	colorless flakes
Active substance, wt %	32	62	93
Disulfonate and polysulfonate, wt %	5	10	14
Sodium chloride, max. wt %	2.0	3.5	4.2
Sodium sulfate	trace	trace	trace
Neutral oil, max. wt %	1.0	1.0	0.5
Iron, max. ppm	5	5	10

Half the chlorine used in the process is converted to low-grade hydrochloric acid, and half into valueless sodium chloride solution. Thus the process is economically inefficient. This disadvantage is offset by the advantage that the highly reactive alkanesulfonyl chloride intermediates can be used in the preparation of a large number of derivatives besides alkanesulfonates. For example, reaction of an alkanesulfonyl chloride with glycine yields and alkylsulfamidocarboxylic acid, which can be used to prepare effective emulsifiers and corrosion inhibitors. Esters, obtained with alcohols and phenols, are used as plasticizers for plastics.

Storage. Alkanesulfonate flakes are hygroscopic and should be processed in total. The pastes undergo segregation on standing and must be homogenized before use. The products can be stored for an unlimited time.

Sulfoxidation Processes. Figure 15 illustrates a production process for alkanesulfonates using the following reactions

Figure 15. Production process flow sheet for alkanesulfonates using sulfoxidation

a) Photoreactor; b) Acid settler; c) Degassing column; d) Evaporation column; e) Separator for sulfuric acid; f) Neutralization vessel; g) Evaporator

$$RH + 2\,SO_2 + O_2 + H_2O \rightarrow RSO_3H + H_2SO_4$$

$$RSO_3H + NaOH \rightarrow RSO_3Na + H_2O$$

When carried out under UV irradiation with addition of water, this process is known as the light – water process.

The reactors must be resistant to acids and oxidation, and are of large volume in order to maximize the quantum yield. High-pressure 10 – 40 kW mercury vapor lamps are used. The protective tubes are made of quartz and are double-walled to absorb the thermal radiation from the lamp, with water cooling being provided between the lamp and reaction space. Since oxygen is substantially less soluble than sulfur dioxide in alkanes the reaction gas must be circulated at a high rate with a blower to maintain a sufficient supply of dissolved oxygen in the reaction mixture. This circulating gas also ensures intensive mixing of the reactor contents, which, however, can also be achieved by powerful stirrers. This is important because the aqueous and alkane phases must be constantly mixed so that the alkanesulfoperoxyacid formed initially comes into immediate contact with water and sulfur dioxide, whereby it is decomposed to the alkanesulfonic acid. Furthermore, the aqueous phase constantly extracts sulfonic acids and sulfuric acid from the alkane phase. The unusually high degree of polysubstitution — with a 1 % paraffin conversion the sulfonic acids formed already contain 10 % of disulfonic and polysulfonic acids — is due to the multiphase nature of the system. To avoid a higher proportion of disulfonic acids, the alkane conversion is limited to ca. 1 %. The mixture leaving the reactor, which consists of about 25 parts of alkane and one part of aqueous phase, passes to a separator in which the alkane forms the upper phase. The alkane is recycled through a cooler to the reactor, together with fresh alkane and process water. At 1 % conversion the amount of recycled alkane is very large, and can be used for external cooling of the reaction mixture. The reaction temperature is maintained at 20 – 40 °C.

The acid phase that separates out in the settler contains acids (sulfonic acids and sulfuric acid), water, and alkane in roughly equal amounts. This phase is freed from dissolved sulfur dioxide by degassing and is concentrated by distilling off part of the water under vacuum. The low-water- content bottom product from the evaporating column separates into two phases, the lower phase consisting of 50 to 65 % aqueous sulfuric acid, which is thereby largely removed from the sulfonic acid phase. Discolorations, which can occur in this stage due to heating (60 – 120 °C) of the sulfonic acids, can be counteracted by addition of hydrogen peroxide. The organic phase remaining after separating the sulfuric acid consists of roughly equal parts of sulfonic acids and alkane. It is neutralized with concentrated sodium hydroxide and freed from residual alkane, e.g., in a thin-layer evaporator at 200 °C in vacuo, which is recycled to the reaction. The sulfonate melt that is formed can be cooled on a rotating drum and converted to flakes, or processed with water into 60 – 65 % pastes.

As an alternative to the thermal separation of sulfuric acid, the sulfonic acids together with the alkane can be extracted from the mixture with weakly polar solvents such as alcohols, ketones, or ethers, leaving behind a 20 % aqueous sulfuric acid. The solvent must then be separated after the neutralization in an additional distillation column [58].

Some data for commercial products of various concentrations are listed in Table 8.

Table 8. Typical characteristic data of industrial sodium alkanesulfonates [85711-69-9], [7757-82-6], and [7732-18-5] obtained by the sulfoxidation process

	Concentration		
	30 %	**60 %**	**93 %**
Appearance at 25 °C	clear, almost colorless liquid	yellowish, soft paste	yellowish, waxy flakes
Active substance, wt %	30	60	93
of which disulfonate and polysulfonate, wt %	4	7	11
Sodium sulfate, max. wt %	2	4	6.5
Alkane, max. wt %	0.3	0.5	0.7
APHA color (10 % active substance in water)	40	40	50
Bulk density, g/L			500

Storage and Dispatch. The flake product can be stored for an unlimited period without undergoing any change provided moisture is excluded. The 60 % paste tends to undergo phase separation, which is prevented by stirring or circulation with a pump at 65 °C. The 30 % solution remains homogeneous and is easily pumpable.

Stainless steel, aluminum, and glass fiber reinforced polyester resin are suitable materials for storage tanks and pipelines. Normal steel is unsuitable because even very small amounts of rust seriously affect the quality.

Producers. Alkanesulfonates are produced by the sulfochlorination process by Bayer, Leuna and at Volgograd (Russia), and by the sulfoxidation process by Hoechst and Hüls.

6.2.4. α-*Olefinsulfonates [59-63]*

Olefinsulfonates are obtained by hydrolysis and neutralization of the sulfonation products of olefins. Suitable sulfonating agents include sulfur trioxide and its complexes (e.g., with dioxan), and chlorosulfonic acid; gaseous sulfur trioxide is used exclusively in industry. The fact that only α-olefins are used for the production of sulfonates is due primarily to the availability of C_{12} – C_{18} olefins of this type in the required degree of purity. Since the sulfonation takes place without double bond isomerization, α-sulfonates (α-olefinsulfonates = AOS) having good application properties are obtained from α-olefins. If olefins containing a centrally situated double bond are sulfonated, sulfonates with a centrally bonded sulfonate group are obtained, which have not yet achieved any industrial importance [64], [65].

In the sulfonation of α-olefins 1,2-sultones are probably formed initially, which then isomerize rapidly to 1,3-sultones, and more slowly to 1,4-sultones:

In the reaction with sulfur trioxide diluted with inert gas, at temperatures up to 40 °C, almost exclusively sultones are formed at up to 60 % olefin conversion, and at higher conversions the sultones isomerize to some extent to alkenesulfonic acids:

With increasing conversion side reactions such as disulfonation and oxidation also increase, leading to discoloration of the product. To convert the sultones completely to sulfonic acids or sulfonates, the sulfonation mixture must be hydrolyzed. Hydrolysis can be performed under acid or alkaline conditions. Acid hydrolysis gives predominantly alkenesulfonic acids with double bonds in the 2- and 3-positions, though compounds with more internal double bonds are also obtained; in alkaline hydrolysis about two-thirds of the reaction product consists of salts of hydroxyalkanesulfonic acids, and the remainder, salts of alkenesulfonic acids, as isomer mixtures:

Industrial hydrolysis is carried out exclusively under alkaline conditions, mixtures of 60 to 65 % of alkenesulfonates and 40 – 35 % of hydroxyalkanesulfonates being obtained, which for the sake of simplicity are termed α-olefinsulfonates.

β-Branched α-olefins, formed by dimerizing short- chain α-olefins, are sulfonated either as such, but generally mixed with linear α-olefins. Due to the presence of a tertiary carbon atom, exclusively β-branched isomeric alkenesulfonic acids are obtained, e.g.,

Since they have a long- chain hydrophobic residue and a terminal hydrophilic group, α-olefinsulfonates derived from linear α-olefins are efficient surfactants, with low CMCs, high detergent power, and good foaming ability in water. On account of their good water solubility sulfonates obtained from 1-dodecene to 1-hexadecene are widely used in liquid detergents and cleansing agents, in cosmetic preparations, and shampoos. Sulfonates obtained from α-hexadecene to α-octadecene can be used in powder formulations. Sulfonates obtained from β-branched α-olefins are only slightly watersoluble; they are good wetting agents, but are less suitable for detergents and cleansing agents. In industrial products they are used as a blend with linear α-olefin sulfonates in a maximum proportion of 30 %.

Production. The reaction of sulfur trioxide with olefins is rapid and strongly exothermic (ca. 180 kJ/mole; i.e., for example, 860 kJ/kg hexadecene). Local overheating, which leads to carbonization and thus brown to black products, cannot be avoided in conventional sulfonation reactors, even with intensive cooling and thorough mixing, especially if high olefin conversions are used for economic reasons.

The sulfonation of α-olefins is nowadays carried out industrially in continuous, short-time sulfonation reactors, like those used for sulfonation of alkylbenzene (see Alkylbenzenesulfonates), and for sulfating ethoxylates [51], [52]. The principle of these reactors, supplied by Allied, Ballestra, Chemithon, Lion, or Mazzoni, is to bring the substrate in the form of thin, fast-flowing and strongly cooled films or layers into contact with sulfur trioxide gas diluted with inert gas. Air or residual air from the combustion of sulfur dioxide to sulfur trioxide serves as inert gas; the concentration of sulfur trioxide is adjusted to 4 – 6 vol %.

Figure 16 illustrates the continuous production of a sodium α-olefinsulfonate. The olefin is reacted with a 10 – 20 % excess of sulfur trioxide in the reactor at as low a temperature as possible (40 °C; at lower temperature the high viscosity can cause problems). The reaction product flows into a separator, in which liquid and gas separate. The waste gas, which contains traces of sulfur trioxide and small amounts of sulfur dioxide is washed with caustic soda before being discharged to the atmosphere. The sulfonation mixture is introduced into the circulating stream of neutralized sulfonic acid and mixed with caustic soda in a pump. A partial stream is charged via a booster pump and a heater to a hydrolysis reactor where residual sultones are saponified. Hydrolysis is carried out at 150° to 250 °C with a residence time of < 1 h. If the solution still contains fairly large amounts of unsulfonated hydrocarbon, this separates as upper phase and can be removed. The hydrolysate is cooled and the pressure is released. The amount of water added in the neutralization is measured so that 30 to 40 % solutions are formed, which are bleached with hydrogen peroxide.

Figure 16. Continuous preparation of sodium α-olefinsulfonate

a) Sulfonation reactor; b) Gas separator; c) Mixing pump; d) Booster pump; e) Heater; f) Hydrolysis reactor; g) Pressure maintenance valve; h) Reactor for bleaching

The olefinsulfonates produced in this way contain, relative to total sulfonate, 10 – 15 % of disulfonates and small amounts of neutral oil (olefins, sulfones, oxidation products) and sodium sulfate.

Typical data of two industrial products based on C_{14}/C_{16} and C_{16}/C_{18} α-olefins are summarized in Table 9.

Table 9. Typical data of industrial sodium α-olefinsulfonates

Olefin	C_{14}/C_{16}	C_{16}/C_{18}
CAS no.	[68439-57-6]	[977067-81-4] (RD)
Appearance at 25 °C	clear, pale yellow liquid	slightly turbid, pale yellow liquid
Active substance, wt %	37	33
of which disulfonate, wt %	4	3
Sodium sulfate, wt %	1	1
Sodium chloride	trace	trace
Unsulfonated substance, wt %	1.5	1.5
Klett color index (5 % in 5 % butyl diglycol)	60	100
Viscosity, mPa · s	ca. 1000	ca. 1000

Storage and Dispatch. Olefinsulfonate solutions can be stored and dispatched in stainless steel or plastic vessels. The solutions are pumpable. Olefinsulfonates are not sensitive to heat, though overheating should be avoided. Reversible precipitation can occur below 0 °C.

Producers. α-Olefinsulfonates are produced by Akzo, Albright & Wilson, Hoechst, Rhône-Poulenc, and Witco in Europe; by Pilot Chemicals, Rhône-Poulenc Surfactant, Stepan, and Witco in the United States; and by Lion in Japan. Important producers of α-olefins, which are produced on a large scale for various purposes such as sulfonation, hydroformylation, or alkylation, are Chevron in the United States, Ethyl in Belgium and the United States, Nizhnekamsk in Russia, Shell in England and the United States, Spolana in Czechoslovakia, and Idimitsu Petrochemical in Japan.

6.2.5. α-*Sulfo Fatty Acid Esters [63], [66-70]*

The sodium salts of α-sulfo fatty acid methyl esters based on coconut, palm kernel, or tallow fatty acids are far more soluble in water than the disodium salts of α-sulfo fatty acids:

For this reason the esters are preferred. The α-sulfo fatty acid esters are stable to hydrolysis in the pH range 4 – 9 and are relatively insensitive to water hardness. They have good emulsifying and lime soap dispersing properties, and their aqueous solutions foam well and have a good cleaning ability with respect to textiles. They are accordingly used as components of soap bars and detergents.

The α-sulfo fatty acid esters are prepared by sulfonation of fatty acid methyl esters. The reaction proceeds in two stages [71]. Sulfur trioxide is rapidly absorbed by the ester at < 50 °C to give a 2 : 1 addition compound that rearranges to the α-sulfo fatty acid methyl ester at 70 – 90 °C. Sulfonation with 5 vol % of sulfur trioxide in an inert gas can be carried out in a stirred vessel cascade, in which the temperature increases from vessel to vessel. With sulfonation in a continuous short-time sulfonation reactor, a further reactor must be connected that ensures complete rearrangement at elevated temperature. Sulfonation is carried out with a 10 – 20 % excess of sulfur trioxide. The sulfonation mixtures are dark colored, and are bleached with hydrogen peroxide at 60 to 80 °C and then neutralized with sodium hydroxide. The sodium salts of the α-sulfo fatty acid esters are handled as ca. 40 % pastes or slurries.

Producers. α-Sulfo fatty acid esters are produced by Henkel and Lion.

6.2.6. *Sulfosuccinates [72], [73]*

The sodium salts of sulfosuccinate esters are obtained by reacting dialkyl maleates or salts of monoalkyl maleates with sodium hydrogensulfite in aqueous-alcoholic solution. Esterification components for dialkyl esters are mainly $C_5 – C_8$ alcohols and fatty acid ethanolamides, and for monoalkyl esters, fatty alcohols, fatty acid ethanolamides, and fatty acid ethoxylates. The sulfosuccinates thus offer a wide variety of molecular structure, which can be adapted to numerous applications. The pure sulfo esters are also termed sulfosuccinates, while the amide-group- containing products are known as sulfosuccinamates:

The dialkyl sulfosuccinates with short- chain alkyl groups R such as butyl, hexyl, or ethylhexyl are readily soluble in water and have outstanding wetting power (fast wetters) and dispersing properties, and are therefore used in textile processing and dyeing. They crystallize readily, like the sulfosuccinamates, and are therefore ideally suited as components of dry cleaning agents. With increasing alkyl chain length the solubility and wetting ability of sulfosuccinates decrease, while their detergent power and emulsifying power increase. The disodium salts of monosulfosuccinates are becoming increasingly important as hardness-insensitive and dermatologically compatible surfactants [74]. They are used in detergents and cleansing agents, especially for bodycare products, and as emulsifiers in cosmetics. They are also used as polymerization emulsifiers and in ore flotation. Suitable alkyl residues in these sulfosuccinates are fatty alkyl or nonylphenyl residues; the degree of ethoxylation *n* is between 3 and 12. Natural fatty acids are used as starting products for sulfosuccinamates.

A common feature of all sulfosuccinates is that they are readily saponified at the ester group. They can therefore be used only in approximately neutral media (pH 6 – 8).

Storage and Dispatch. The sodium salts of the diesterified sulfosuccinic acids can be obtained as powders by evaporating their solutions. They are generally transported as concentrated solutions in plastic drums or stainless steel vessels. Table 10 gives some typical data for three industrial products, which may contain a few percent of a solvent (isopropanol) in order to render them clear.

Table 10. Typical data of some industrial sulfosuccinates

	Sodium diethylhexyl sulfosuccinate	Disodium lauryltriglycol sulfosuccinate	Disodium lauroylaminoethyl sulfosuccinate

Producers include Albright & Wilson, Auschem, BASF, Cyanamid, Harcros, Henkel, Hüls, Manro, Rewo, Rhône-Poulenc, Stepan, Union Carbide, Witco, and Zschimmer & Schwarz in Europe; American Cyanamide, Croda, Enkay, Harcros, Hart, Henkel, The McIntyre Group, Mona Industries, Rhône-Poulenc, Sherex, Stepan, and Union Carbide in North America; Zohar in Israel; Toho and Sanyo in Japan; and Taiwan Surfactant in Taiwan.

6.2.7. *Alkoxyalkane-, Acyloxyalkane-, and Acylaminoalkanesulfonates*

Methods of preparation of alkoxyalkanesulfonic acid salts, which would be useful for synthesizing alkylpolyglycol ether sulfonates, which in contrast to ether sulfates are resistant to hydrolysis, have not yet been carried out on an industrial scale.

The reaction of alcohols with epichlorohydrin to form alkoxyhydroxychloropropane, which reacts with sodium sulfite to give an alkoxyhydroxypropanesulfonate, has achieved some importance:

Such sulfonates are stable to water hardness and have good wetting and dispersing properties. They are dermatologically compatible and are used occasionally in the United States in body cleansing agents. Their water solubility, however, is low. Products containing $C_{16} – C_{18}$ alkyl groups are only sparingly soluble.

Due to their insensitivity to water hardness, good foaming power, soil suspending power, and dermatological compatibility, the fatty acid-derived salts of acyloxyethanesulfonic and acylaminoethanesulfonic acids are industrially fairly important (e.g., in the textile industry and in bodycare and cleansing agents). They are prepared by reacting the corresponding acid chlorides with sodium isethionate or *N*-methyltaurine.

$$RCOCl + HOCH_2CH_2SO_3Na \longrightarrow RCOOCH_2CH_2SO_3Na + HCl$$

$$RCOCl + CH_3NHCH_2CH_2SO_3Na + NaOH \longrightarrow RCON(CH_3)CH_2CH_2SO_3Na + NaCl + H_2O$$

Whereas the reaction of the isethionate with the acid chloride takes place at 100 – 120 °C without solvent and the reaction product occurs in a friable solid form after the hydrogen chloride, *N*-methyltaurine is reacted with the fatty acid chloride in aqueous solution at 20 – 30 °C. The *N*-acyl-*N*-methyltauride is obtained as a 30 –40 % solution, which can be converted into an anhydrous powder by drying.

Since the fatty acid chlorides must be synthesized from the fatty acids by reaction with phosphorus trichloride or thionyl chloride, attempts have been made to react the free acids directly with isethionate or *N*-methyltaurine at elevated temperature. Although the desired derivatives of ethanesulfonic acid are formed in 80 – 90 % yield, they are less pure than those obtained from acid chlorides.

Producers. Isethionates are produced in Europe by Hoechst, in the United States by Henkel-Emery, Hoechst-Celanese, and Rhône-Poulenc Surfactant; taurates are produced in Europe by Croda, in the United States by Finitex, Hart, Henkel-Emery, Hoechst-Celanese, Sherex, and Union Carbide, in Israel by Zohar, and in Japan by Nikko Chemicals and Nippon Oil & Fats.

6.3. Sulfates

In surfactant chemistry the term “sulfates” refers to the salts of acidic sulfuric acid esters, R–OSO_3M. In this class of compounds the sulfur atom of the hydrophilic sulfate group is bonded via an oxygen atom to the hydrophobic residue. This ester group is susceptible to hydrolysis, more strongly in acid media than in alkaline media, and is less thermally stable than the analogous sulfonates. Sulfates are prepared by sulfation of hydroxyl- containing substrates with sulfuric acid, oleum, chlorosulfonic acid, sulfuryl chloride, amidosulfonic acid, complexes of sulfur trioxide, or sulfur trioxide itself, or by addition of sulfuric acid to double bonds (⟶ Sulfonic Acids, Aliphatic). A large variety of surfaceactive sulfates is thus available, including the sulfated unsaturated fatty acids and oils that formed the starting point of surfactant chemistry and which still play a role in the textile industry [75], to the sulfates of fatty acid ethanolamides and their ethoxylates, which on account of their dermatological safety are used in cosmetics [76], and to the highly surface-active sulfated monoglycerides of fatty acids [76].

6.3.1. *Alkyl Sulfates [67], [77-79]*

The primary alkyl sulfates developed in the 1930s, based on natural alcohols obtained by hydrogenating fatty acid esters, were the first synthetic surfactants to be produced on an industrial scale. They give a neutral reaction in aqueous solution. Their physicochemical and applicational properties have been investigated intensively, especially the influence of the structure of the hydrophobic group on the above-mentioned properties has been described in detail, since individual defined substances can readily be prepared [79].

The sodium salts of alkyl sulfates prepared from primary, linear alcohols up to C_8 are scarcely surface-active. Industrially important sulfates are derived from dodecyl and tetradecyl alcohols (coconut oil and palm kernel alcohol); these sulfates are water-soluble and resistant to water hardness, and form good detergents, foaming agents, and emulsifiers. Their good dispersant properties are offset by a poor soil-suspending power. The sodium salts of the sulfates of hexadecyl and octadecyl alcohols (tallow fat alcohol) are fairly insoluble in water, especially in hard water; however, because the solubility increases markedly with increasing temperature, these sulfates are very active at elevated temperature (e.g., in textile washing).

In acidic aqueous solution (pH 3 – 4) alkyl sulfates are stable in the cold but hydrolyze on heating. They are stable in hot neutral and alkaline solution.

The primary, linear alkyl sulfates have high thermal stability, and can be spray dried at high temperature without decomposition. In contrast, the sulfates obtained from α-branched, primary and from secondary alcohols are thermally less stable, and readily decompose into sodium hydrogensulfate and alkene.

Due to the more central position of their hydrophilic groups the sulfates of highly branched alcohols obtained by the oxo or Guerbet processes or of secondary alcohols are less suitable as detergents and emulsifiers; however, in aqueous solution they have higher wetting power than the sulfates of linear primary alcohols. Secondary alkyl sulfates are no longer in use.

Production of Alkyl Sulfates. Since esterification of alcohols with sulfuric acid, followed by neutralization

$$ROH + H_2SO_4 \rightleftharpoons ROSO_3H + H_2O$$

is an equilibrium reaction the sulfuric acid must be used in excess to maximize alcohol conversion. Apart from corrosion problems caused by the water formed in the reaction, the separation of the excess sulfuric acid from the reaction mix-ture is a problem. This can be avoided if a slight excess of chlorosulfonic acid is used as sulfating agent:

$$ROH + ClSO_3H \rightarrow ROSO_3H + HCl$$

The gaseous hydrogen chloride formed is absorbed in water or sodium hydroxide. The reaction with chlorosulfonic acid must be carried out at the lowest possible temperature to avoid side reactions. Residual hydrogen chloride can be removed from the reaction mixture almost completely by air sparging.

Although sulfation with chlorosulfonic acid is still carried out in small production units, sulfation with sulfur trioxide diluted with inert gas is the method of choice for large-scale plants. In the same way as in the already discussed preparation of α-olefinsulfonates (see Section α-Olefinsulfonates), this reaction can be carried out in a continuously operating short-time sulfonation reactor [51], [52]. Sulfation is performed with equimolar amounts of sulfur trioxide; an excess promotes side reactions and discoloration of the product. Since elevated temperatures have the same effect, the reaction temperature should be below 50 °C. The reaction product leaving the reactor is degassed and neutralized as quickly as possible, preferably with sodium hydroxide:

$$ROH + SO_3 \rightarrow ROSO_3H$$

$$ROSO_3H + NaOH \rightarrow ROSO_3Na + H_2O$$

Often, the product is bleached with hydrogen peroxide.

The fatty alkyl sulfates are generally commercially available as 30 % pastes; above this concentration highly viscous pastes form, which are difficult to handle. The linear, primary alkyl sulfates crystallize well and are therefore also handled as powders that have been dried on rollers or in the spray process. Characteristic data of some industrial alkyl sulfates are listed in Table 11.

Storage and dispatch conditions correspond to those of the alkylbenzenesulfonates (see Storage and Dispatch.) or alkanesulfonates. The products must not be heated too strongly since they may be acidified further due to hydrolysis.

Producers of fatty alkyl sulfates include Akzo, Albright & Wilson, Auschem, Berol Nobel, Chem-Y, Harcros, Henkel, Hüls, Manro, Rewo, Stepan, Unger, Witco, and Zschimmer & Schwarz in Europe; Du Pont, Emkay, Henkel, Lonza, Rhône-Poulenc Surfactant, Stepan, Unger, and Witco in the United States; Daiichi, Kao, Nippon Oil & Fats in Japan; and Zohar in Israel.

Leading producers of the fatty alcohol starting materials by fatty ester hydrogenation are: Henkel, Hüls, Marchon, Oleofina, Rodleben, RWE-DEA in Europe; Procter & Gamble and Sherex in the United States; Kao and New Japan in Japan, and joint ventures of local and Western companies in the Philippines and Malaysia. Ethylene-base Ziegler alcohols are produced by RWE-DEA in Germany and by Ethyl in the United States. Important producers of oxo alcohols by hydroformylation of olefins are BASF, Enichem, Exxon, ICI, Shell in Europe, and Shell and Vista in the United States.

6.3.2. *Ether Sulfates [67], [77], [80-83]*

Ether sulfates is the short name for salts of sulfuric acid hemi-esters of alkyl or alkylaryl oligoglycol ethers of general formula

$$RO[CH_2CH_2O]_nSO_3Na$$

The oligoglycol ethers, namely ethers of oligooxyethylenes or ethoxylates, on which the ether sulfates are based are homologous mixtures where n = 0, 1, 2 . . . , etc.; the number n in the above formula specifying the mean degree of ethoxylation. Industrial ether sulfates are accordingly also homologous mixtures; with increasing degree of ethoxylation the content of alkyl sulfate (n = 0) decreases.

The oligoglycol group of the ether sulfates results in better water solubility and higher stability to water hardness, compared to sulfates containing the same alkyl or alkylaryl group. The most important surfactants of this group are the alkyl ether sulfates derived from ethoxylates of dodecanol and tetradecanol (coconut and palm kernel fatty alcohols) with a mean degree of ethoxylation of 2 – 4. Instead of natural alcohols, synthetic fatty alcohols are also used in the corresponding C- cut range. These ether sulfates have achieved considerable importance due to their good stability to hard water, dermatological compatibility, foaming and detergent power, their good emulsifying and lime soap dispersing power, their rheological behavior, and also on account of synergistic effects that they exhibit in conjunction with some other anionic surfactants (sulfonates). They are used in cosmetic preparations, foam baths, shampoos, liquid detergents, cleansing agents, especially fine detergents and rinsing agents, generally in combination with other surfactants. Being sulfuric acid hemi-esters, ether sulfates can be saponified only with difficulty in alkaline media, but are readily saponified under acid conditions. Slow saponification also occurs in neutral media, but since sodium hydrogensulfate is produced the solution becomes increasingly acidic and the saponification is thereby accelerated autocatalytically:

$$RO[CH_2CH_2O]_nSO_3Na + H_2O \rightarrow RO[CH_2CH_2O]_nH + HOSO_3Na$$

Solutions of ether sulfates are protected against this autocatalytic decomposition by adding citrate, lactate, or phosphate buffers.

A well known property of ether sulfates is the thickening effect, i.e., the increase in viscosity by several orders of magnitude of even dilute solutions on adding electrolytes. The increase in viscosity passes through a maximum, depending on the electrolyte concentration in the solution; the effect also depends on the concentration and structure of the ether sulfate (Fig. 17).

Figure 17. Thickening of 10 % aqueous solutions of fatty alcohol ether sulfates containing 3 mol EO/mol, as a function of the structure of the fatty alcohol residue

a) C_{12}/C_{14} 100 % linear; b) C_{12}/C_{15} 90 % linear; c) C_{12}/C_{15} 50 % linear; d) C_{12}/C_{15} 10 % linear

Production. Ether sulfates are obtained by sulfation of the corresponding ethoxylates and neutralization of the resulting sulfuric acid hemi-esters. Sulfuric acid is no longer used for sulfation, because it must be added in excess and remains in the product as sodium sulfate after neutralization. In smaller production units sulfation is performed with chlorosulfonic acid, as described for the preparation of primary alkyl sulfates (see Production of Alkyl Sulfates.), and the neutralized product then contains a few percent of sodium chloride. Amidosulfonic acid is occasionally used as sulfating agent, with the advantage that no byproducts or waste products are formed. In this case, however, ammonium ether sulfates are obtained:

$$RO[CH_2CH_2O]_nH + HSO_3NH_2 \rightarrow RO[CH_2CH_2O]_nSO_3NH_4$$

Amidosulfonic acid is preferably used in the sulfation of alkylphenyl ethoxylates, since in this way sulfonation of the aromatic nucleus is largely avoided.

Ether sulfates are now mainly produced by continuous sulfation of ethoxylates in short-time sulfonation reactors using gaseous sulfur trioxide, and continuous neutralization (see preparation of alkylbenzenesulfonates and olefinsulfonates, Sulfonation.). The sulfation mixture should be neutralized as quickly as possible since decomposition and disproportionation reactions occurring in the acidic reaction mixture lead to accumulation of byproducts, reduction of the content of active substance, and darkening of the color.

One of the decomposition products is 1,4-dioxane, a suspected carcinogen (⟶ Dioxane). The dioxane content can be kept below 50 ppm by precise control of the sulfation reaction (maintenance of low temperature, avoidance of excess sulfur trioxide, dilution of the sulfur trioxide gas, maintaining uniform throughput with optimum mixing and minimum residence time) as well as rapid degassing and neutralization [84], [85].

Even when the reaction is carefully controlled, the ether sulfates are not colorless. They exhibit a self-bleaching effect for several days when allowed to stand in air, presumably due to autooxidation processes. The products are normally rebleached with hydrogen peroxide or sodium hypochlorite.

Typical data of industrial sodium salts of ether sulfates are listed in Table 12.

Storage and Dispatch. Up to 30 % aqueous ether sulfate solutions are stored and transported in plastic containers or in plastic-lined vessels. Aluminum vessels are also suitable for short-term transportation. Phase separation may occur during storage in the cold, which can be prevented by stirring.

Alkyl ether sulfates in aqueous solutions of between 25 and 30 % concentration exhibit a sharp rise in viscosity from ca. 100 mPa · s to ≥ 100 000 mPa · s. This viscosity reaches a maximum value between 40 and 50 %, then decreases to 10 000 mPa · s at 60 – 70 % concentration (Fig. 18). Since pastes of this viscosity are still pumpable, 60 – 70 % products are also marketed.

Figure 18. Viscosity of an alkyl ether sulfate as a function of its concentration [80]

The concentration-dependent viscosity behavior makes precautionary measures necessary when diluting concentrated pastes with water, so as to avoid the high-viscosity gel

state at 40 –50 % concentration. Dilute solutions are best prepared by adding the concentrated paste to water.

Producers include Akzo, Albright & Wilson, Auschem, Berol Nobel, Chem-Y, Harcros, Henkel, Hüls, Manro, Pulcra, Rewo, Rhône-Poulenc, Shell, Unger, Witco, and Zschimmer & Schwarz in Europe; Clough Chemical, Henkel, Niacet, Pilot Chemicals, Rhône-Poulenc Surfactant, Sandoz, Stepan, and Witco in North America; Kao, Lion, Marubishi Oil Chemical, Nikko Chemicals, Nippon Nyu Kazai, Nippon Oil & Fats, and Sanyo in Japan; and Zohar in Israel.

6.4. Alkyl Phosphates [86-88]

Acid phosphate esters and their salts are prepared by reacting alcohols or ethoxylates with phosphorus pentoxide:

$$3\,\mathrm{ROH} + \mathrm{P_2O_5} \rightarrow \mathrm{ROPO_3H_2} + (\mathrm{RO})_2\mathrm{PO_2H}$$

followed by neutralization, if required.

Alkyl phosphates thus generally consist of mixtures of monoalkyl and dialkyl esters of phosphoric acid. Monoalkyl, dialkyl, and trialkyl esters can specifically be prepared by stepwise reaction of a hydroxyl compound with phosphoryl chloride, followed by saponification of the resulting phosphoric ester chlorides.

Phosphoric partial esters with short- chain alkyl groups (e.g., butyl phosphoric acids) are strong acids, which have corrosion-inhibiting and bactericidal action. They are readily soluble in hard water and act as wetting and dispersing agents, and are therefore used in acid-adjusted cleansing agents, e.g., for vehicles or swimming baths.

The water solubility and acid strength of phosphoric partial esters decrease with increasing length of the alkyl chain. The sodium salts of long- chain alkyl phosphoric acids readily dissolve in water, have low sensitivity to water hardness, and are resistant to saponification, especially in alkaline media. They are good wetting agents and emulsifiers; the salts of monoalkyl phosphoric acids inhibit foam formation by other anionic or nonionic surfactants. Since the phosphates also have high dermatological compatibility, they are used both in highly alkaline cleansing agents, and in general cleansing agents, including body cleansing agents (the latter especially in Japan).

Producers of alkyl phosphates include Albright & Wilson, Auschem, BASF, Berol Nobel, Croda, Finetex, Harcros, Henkel, Hoechst, Hüls, Pulcra, Rewo, Rhône-Poulenc, Witco, and Zschimmer & Schwarz in Europe; Climax Performance, Croda, Dexter, Graden Chemical, Harcros, Hart, Henkel, Intex, Lonza, Mona Industries, Norman & Fox, Olin, PPG/Mazer, Reilly Whiteman, and Rhône-Poulenc Surfactant in North America; Kao, Nikko Chemicals, Takemoto Oil & Fat, and Yoshimura Oil Chemicals in Japan; and Taiwan Surfactant in Taiwan.

[Top of Page]

7. Nonionic Surfactants [89-91]

The polarity of covalently bonded oxygen atoms in oligoethylene glycol ethers (also termed polyglycol ethers) and oligohydroxy compounds or of oxygen atoms bonded in a semipolar manner to a heteroatom imparts water solubility and interfacial activity to hydrophobic parent structures to which such oxygen- containing hydrophilic groups are bonded. The most important nonionic surfactants are the ethoxylates, which are formally condensation products of hydrophobic alcohols, phenols, mercaptans, amines, carboxylic acids, carbonamides, etc., with oligoglycol ethers, the fatty acid esters of glycerol, diglycerol, sugars, hydrogenated sugars such as sorbitol, and alkyl(poly) glucosides. Nonionic surfactants with semipolar bonded oxygen as hydrophilic group include fatty amine oxides such as lauryldimethylamine oxide, which is used to a limited extent in liquid cleansing agents, as well as the industrially unimportant sulfoxides and phosphine oxides.

7.1. General Properties

Nonionic surfactants are colorless substances, but may be colored pale yellow to brown depending on the production process. Low molecular mass products are liquid, and with increasing molecular mass the products have a pasty to waxy consistency. In the anhydrous state, especially in the case of ethoxylates, the oligoglycol ether chains of short- chain ethoxylates are present in a stretched zig-zag form, while those of long- chain ethoxylates have a meandering structure, which is also formed in the micelles in aqueous solution.

Nonionic surfactants are less sensitive to water hardness than anionic surfactants. Their aqueous solutions foam less strongly than those of many anionic surfactants. The possible applications of nonionic surfactants are universal, given the large variability of their structure and thus of their properties. The differences between the individual types of nonionic surfactants are slight, and the choice is primarily governed having regard to the costs of special properties, e.g., effectiveness and efficiency, toxicity, dermatological compatibility and biodegradability, or permission for use in foodstuffs. The solubility of nonionic surfactants in water results from hydration of the oxygen groups by hydrogen bonding. The degree of hydration decreases with increasing temperature, and the water solubility of nonionic surfactants therefore decreases with increasing temperature. In the case of surfactants that dissolve in water to give a clear solution, i.e., ethoxylates with a fairly high degree of ethoxylation, turbidity and separation of a surfactant phase that is immiscible with water occur at a specific temperature characteristic of the surfactant (cloud point).

The cloud point can be determined for water-insoluble ethoxylates by dissolving the surfactant in aqueous butyl diglycol. For highly water soluble ethoxylates whose solutions do not become turbid even on boiling, the cloud point can be determined in aqueous sodium chloride solution. Figure 19 shows the cloud point of industrial fatty alcohol ethoxylates as a function of the degree of ethoxylation in 25 % butyl diglycol solution, in fully deionized water, and in 10 % sodium chloride solution.

Figure 19. Cloud point of ethoxylates of a C_{12}/C_{14} fatty alcohol (linear) as a function of the degree of ethoxylation (mol EO/mol)

a) 10 % solution in 25 % butyl diglycol; b) 2 % solution in demineralized water; c) 2 % solution in 10 % NaCl

Correlations exist between the cloud points and the hydrophilic – lipophilic balance (HLB) values or phase inversion temperatures of emulsions with the corresponding surfactants as emulsifiers [92].

The concept of an HLB is of practical value [93].

The HLB system enables nonionic surfactants to be arranged on a value scale from 0 to 20. In the ideal case the HLB value of a surfactant is defined as the ratio of the molecular mass of the hydrophilic fraction in the molecule M_h to the total molecular mass M of the surfactant, multiplied by 20:

$$\mathrm{HLB} = 20 \cdot \frac{M_h}{M}$$

The HLB scale allows rough classification of nonionic surfactants according to their solubility in water and their possible areas of application. Table 13 provides a summary.

Table 13. HLB values of nonionic compounds

HLB range	Behavior in water	Example of use	Example	HLB value
0 – 3	Insoluble	defoaming agent, dispersant for solids in oil, co-emulsifier, refatting agent	Glycerol trioleate Glycerol dioleate Glycerol monooleate	0.8 1.5 2.7
3 – 6	Insoluble, dispersible	water-in-oil emulsions, co-emulsifier	Glycerol monostearate	3.8
			Propylene glycol monolaurate	4.5
			Diethylene glycol monolaurate	6.0
6 – 9	Dispersible, giving milky solution	wetting agent, water-in-oil emulsions	Sorbitan monopalmitate	6.7
			Sorbitan monomyristate	7.6
			Sorbitan monolaurate	8.6
8 – 10	Soluble, giving milky turbid to translucent solutions	wetting agent	Isotridecanol ethoxylate with 3 EO *	8.3
			Isotridecanol ethoxylate with 4 EO	10.0
			Isotridecanol ethoxylate with 5 EO	11.2
10 – 13	Soluble giving translucent to clear solutions	oil-in-water emulsions, detergents and cleansing agents	Isononylphenol ethoxylate with 5 EO	10.7
			Isononylphenol ethoxylate with 6 EO	11.5

			Isononylphenol ethoxylate with 7 EO	12.3
13 – 15	Soluble, giving clear solution	oil-in-water emulsions, detergents and cleansing agents	Octadecanol ethoxylate with 10 EO	13
			Octadecanol ethoxylate with 12 EO	14
			Octadecanol ethoxylate with 16 EO	15
> 15	Soluble, giving clear solutions	solubilizer, cleansing agent	Dodecanol/tetradecanol ethoxylate with 13 EO	15
			Dodecanol/tetradecanol ethoxylate with 17 EO	16
			Dodecanol/tetradecanol ethoxylate with 25 EO	17
			Dodecanol/tetradecanol ethoxylate with 38 EO	18

* Moles ethylene oxide per mole.

The HLB values can be determined by emulsification tests and comparison with emulsifiers of known HLB values (see also ⟶ Emulsions).

7.2. Ethoxylates

Ethoxylates are generally obtained by addition of ethylene oxide to compounds containing dissociating protons.

Substrates used for ethoxylation are primarily linear and branched, primary and secondary C_{12} – C_{18} alcohols, i.e., natural and synthetic fatty alcohols, alkylphenols with branched octyl (butene dimer), nonly(propylene trimer) or dodecyl(propylene tetramer) groups, fatty acids, fatty acid ethanolamides, fatty amines, and fatty acid esters of polyhydroxyl compounds. The degree of ethoxylation, i.e., the molar ratio of ethylene oxide added per mole of substrate, varies within wide ranges, in general between 3 and 40, and is chosen according to the intended use (HLB value, Table 13).

The addition of ethylene oxide to a substrate containing acidic hydrogen is catalyzed by bases or (Lewis) acids.

Amphoteric catalysts, prepared in situ and probably existing as finely dispersed solids having a large surface area [94], as well as heterogeneous catalysts [95], have also been described.

The reaction mechanisms of base- catalyzed and acid- catalyzed ethoxylation differ, which affects the composition of the reaction products. In base- catalyzed ethoxylation an alcoholate anion formed initially by reaction with the catalyst (alkali metal, alkali-metal oxide, carbonate, hydroxide, or alkoxide), nucleophilically attacks ethylene oxide. The resulting anion of the ethylene oxide addition product can undergo an equilibrium reaction with the alcohol starting material or ethoxylate product, or can react further with ethylene oxide:

As this simplified reaction scheme illustrates, in alkaline- catalyzed ethoxylation several reactions proceed in parallel, the addition of ethylene oxide to an anion with the formation of an ether bond being irreversible.

Proton exchange between various anions, occurring as an ionic reaction, is fast; the addition reaction of ethylene oxide to an existing anion is the rate-determining step. Thus in a reaction mixture, the more acidic species preferentially react with ethylene oxide. If carboxylic acids or phenols are ethoxylated, the reaction proceeds exclusively via the left-hand path in the above scheme, and the initially formed monoethylene glycol ester or ether only reacts further when all the starting material in the reaction mixture is consumed. The fast equilibrium proton exchange reaction which precedes the addition of the ethylene oxide to the anionic species leads to a peculiarity of the reaction rate in the case of strongly acidic substrates such as carboxylic acids or phenols. On account of the lower nucleophilicity of their conjugate bases corresponding to the acidic parent substances, these bases react relatively slowly with ethylene oxide; thus, the reaction proceeds slowly until the starting material is consumed. Thereafter the reaction rate increases sharply with further supply of ethylene oxide since the ethoxylate anions now present react substantially more quickly with ethylene oxide than do the anions of the carboxylic acids or phenols [96].

The situation is different in the ethoxylation of alcohols. The ether oxygen atoms in alkyl (oligo)glycol ethers increase the acidity of the terminal primary hydroxyl group compared to the initial alcohol; glycol ethers once formed thus react preferentially with ethylene oxide and lead to the formation of a mixture of homologous oligoglycol ethers, and unreacted starting alcohol remains in the reaction mixture up to high degrees of ethoxylation. This is particularly true for the ethoxylation of secondary alcohols.

Assuming the same acidity of the starting alcohol and all (oligo)glycol ethers present in the mixture, a Poisson distribution of the individual species must be expected in the ethoxylation, with a maximum corresponding to that oligoglycol ether in which the number of added ethylene oxide units corresponds to the molar ratio of ethylene oxide to starting alcohol. However, on account of the aforementioned different acidities of the individual species in the reaction mixture the homologue distribution that is actually observed in an ethoxylation mixture differs from the Poisson distribution (Fig. 20).

Figure 20. Homologue distribution of a lauryl ethoxylate containing 6 mol EO/mol [97]

a) Acid catalysis; b) Base catalysis

This is true for all alkaline catalysts, although the deviations in the case of alkaline-earth compounds are less strongly pronounced than in the case of sodium hydroxide or sodium methoxide [97]. The distribution pattern of the homologous polyethylene glycol ethers in an ethoxylate obtained by alkaline catalysis is independent of the temperature, pressure, and catalyst concentration [98], [99]. The occasionally observed dependence of the homologue distribution on the stirring rate can be attributed to an insufficiently complete mixing of the reactor contents.

When Lewis acids such boron trifluoride, tin tetrachloride, or antimony pentachloride are used as catalysts, homologue distributions approximating to the Poisson distribution are obtained (Fig. 20), because here it is not the proton activity but the nucleophilicity of the substrate that determines the reaction pathway. Lewis acids activate ethylene oxide and not the alcohol:

Lewis acids have not become established as catalysts since they must be laboriously removed from the reaction product and because they lead to the formation of polyethylene

glycol [the so- called polydiol, $HO(CH_2CH_2O)_nH$], methyldioxolane and dioxane, due to side reactions and decomposition reactions.

Since ethoxylates with a narrow, Poisson-like homologue distribution, so- called narrow range ethoxylates (NRE), have advantages in some applications, amphoteric catalysts have been developed that give distributions similar to those produced by Lewis acids [94].

Among these catalysts a calcined hydrotalcite of idealized empirical formula $Mg_6Al_2O_5(OH)_2$ is of interest since it can readily be handled as a pneumatically conveyable powder and can easily be separated as an insoluble solid from the reaction medium [95].

Advantages of narrow range ethoxylates, which also have a substantially lower content of starting alcohol, include: less odor, better solubility, lower volatility (reduced pluming on spray drying) and better thickening properties of both the ethoxylates and the ether sulfates derived therefrom [100-102]. However, broad distributions may also be advantageous, for example, in emulsification processes [103].

The large variability of the hydrophobic group — straight- chain and branched fatty alcohols, alkylphenols, fatty amines, fatty acids and fatty acid (alkanol)amides — as well as the option to achieve any desired degree of ethoxylation, make the ethoxylates an extremely versatile class of surfactants. The ethoxylates of fatty alcohols and alkylphenols as such or in combination with anionic, occasionally also cationic surfactants, play a major role in detergents and cleansing agents. Objections have been raised against the use of alkylphenol ethoxylates on the basis of ecotoxicological findings, which has led to their discrimination in some European countries [104]. When adjusted to the necessary HLB value by means of the degree of ethoxylation, fatty alcohol ethoxylates are used as emulsifiers in cosmetics formulations, dry cleaning, crop protection agents, metal working and processing, and textile auxiliaries, paints and coating compositions. Like the alkylphenol ethoxylates, they are also used as dispersants in petroleum production and in ores flotation. Fatty acid polyglycol esters have numerous uses as emulsifiers in bodycare products and in textile treatment. The same is also true of fatty acid alkanolamides and their ethoxylates, which moreover are used as antistatics in plastics processing and as emulsifiers and corrosion inhibitors in metal working and processing. Finally, fatty amine ethoxylates are used as finishing agents and antistatics in textile treatment and leather processing, and as emulsifiers in the petroleum industry and bitumen production.

General Production Processes. Molecularly uniform ethoxylates can be prepared by the Williamson ether synthesis. Industrial ethoxylates, obtained by ethylene oxide addition are mixtures of homologues. These mixtures generally have superior application properties to molecularly uniform substances.

Special safety precautions must be adopted in industrial ethoxylation. Ethylene oxide, *bp* 10.7 °C, is stored, transported, and metered as a liquid under pressure. The flash point is – 57 °C, the ignition temperature in air is 429 °C, and the decomposition temperature of pure ethylene oxide vapor is 571 °C. The heat of polymerization of ethylene oxide, which is released during ethoxylation, is 2090 kJ/kg; 1900 kJ/kg is released in the decomposition of ethylene oxide vapor. In ethoxylation processes the reaction can run out of control if there is overheating and a consequent rise in pressure; ethylene oxide tends to ignite or undergo self-decomposition (e.g., on overheated stirrer or pump shafts). Ethoxylation must therefore be carried out under strict pressure and temperature control. The reactors must be safe-guarded against excessive pressure by means of safety valves or rupture disks. The excess of ethylene oxide in the reaction mixture must be kept low. On account of the limited solubility of ethylene oxide in the reaction medium the presence of a second, liquid ethylene oxide phase in the reaction vessel must be avoided. The storage vessel from which the ethylene oxide is metered into the reaction vessel must be protected against backflow of reactants containing polymerization-initiating catalyst, e.g., by nonreturn valves and intermediate vessels.

Industrial ethoxylations are carried out mainly in a batchwise manner. Stainless steel pressure vessels are used as reactors. The substrate together with the catalyst, generally sodium hydroxide, is first placed in the vessel. The water introduced with the sodium hydroxide solution and the water formed in the reaction

$$ROH + NaOH \rightleftharpoons RONa + H_2O$$

is removed by heating and applying a vacuum or by passing nitrogen through the reaction mixture, to avoid formation of polyglycols ("polydiols"). Polydiols do not, in general, affect the properties of ethoxylates provided their concentration does not exceed a few percent, but not being surface-active they result in a wastage of ethylene oxide. The catalyst content is usually 0.1 – 1.0 %. The ethoxylation is carried out between 130° and 180 °C, and the substrate first must be heated up to this temperature. The reactor contents must be cooled during the addition of ethylene oxide. Heating and cooling can be performed by external jackets, internal tubes or by heat exchangers through which the reactor contents are constantly pumped.

The gaseous phase is inertized by diluting it with nitrogen. The reaction is carried out at 1 –5 bar gauge pressure. The liquefied ethylene oxide is metered into the reaction medium with intensive mixing. The temperature and pressure are monitored so that the ethylene oxide supply can be adjusted if the reaction becomes quiescent or goes out of control. The desired degree of ethoxylation is adjusted via the amounts of substrate and ethylene oxide.

The product specifications can quickly be checked by determining the cloud point.

The reaction time depends on the effectiveness of cooling and amount of ethylene oxide to be added; the production of an ethoxylate having a medium degree of ethoxylation takes a few hours in conventional stirred vessels provided with internal cooling.

The catalyst is neutralized with carbon dioxide, acetic acid, or citric acid. Phosphoric acid gives a precipitate that can be filtered off, but in most cases the neutralized catalyst remains dissolved in the product. Any slight discoloration of the products can be removed by bleaching with hydrogen peroxide.

The products are discharged hot into stainless steel storage tanks or vats, or are cooled in the reactor and discharged into plastics vessels.

Discoloration and polydiol concentration increase with increasing reaction temperature. The formation of polydiols is due to increasing elimination of water from ethoxylates as the temperature rises:

$$RO-[CH_2CH_2O]_n-OCH_2CH_2OH \longrightarrow RO-[CH_2CH_2O]_n-OCH=CH_2 + H_2O$$

$$H_2O + n\overset{O}{\overset{/\backslash}{CH_2-CH_2}} \longrightarrow HO-[CH_2CH_2O]_n-H$$

Further impurities can be formed by reactions of other compounds introduced with the ethylene oxide (e.g., formaldehyde and acetaldehyde).

Although continuous ethoxylation processes are also described in the literature [105], industrial ethoxylations, like other alkoxylations, are mainly carried out as batch operations.

The Pressindustria alkoxylation process for addition of ethylene oxide and/or propylene ox-ide operates according to a different principle than the stirred vessel method (Fig. 21). The liquid reaction mixture, circulated at high speed, is dispersed by a special device in a gas phase consisting of ethylene oxide (possibly also propylene oxide), ensuring rapid absorption of ethylene oxide [106], [107]. Catalyst and substrate are mixed in a heated receiving vessel and freed from water by heating under vacuum. This mixture is passed to the reactor and circulated by means of a pump through the special mixing unit (c) and the reactor. The mixture is heated to reaction temperature in the heat exchanger (e); residual moisture is removed by applying a vacuum or passing nitrogen through the mixture. The addition of ethylene oxide then starts, the ethylene oxide being flashed into the gas phase of the mixer (c). Here the liquid reaction mixture introduced in finely dispersed form adsorbs the ethylene oxide. The reaction proceeds in the liquid phase in the mixer and reactor, into which the liquid phase flows from the mixer. The heat of reaction is dissipated by the cooler (f). When the desired degree of ethoxylation is reached the product is passed to the neutralization vessel. The reaction is carried out at 180 – 190 °C, and a maximum pressure of 5 bar.

Figure 21. Pressindustria alkoxylation apparatus [106]

a) Receiving vessel; b) Reactor; c) Mixer for gas and liquid; d) Circulating pump; e) Heater; f) Cooler; g) Neutralization vessel

The process has a high reaction rate and uniform product quality. The safety risks involved with gaseous ethylene oxide are minimized by keeping the gas phase as small as possible. Since this part of the reactor contains no moving parts, ignition of the gas phase by shafts, for example, overheating, is ruled out. This process can also be operated continuously.

High reaction rates and low formation of byproducts can also be achieved in a jet nozzle reactor or jet suction reaction mixer [108].

Production of Ethoxylates of Fatty Acids, Fatty Acid Amides, and Fatty Amides. All industrial products based on primary alcohols or alkylphenols can be ethoxylated by the above processes.

In the ethoxylation of fatty acids the transesterification of the initially formed oligoglycol esters that is unavoidable with alkaline catalysis leads to the formation of diesters and free oligoglycols, which in the further course of the ethoxylation lead to undesirably high polydiol contents in the end product:

$$2\ RCOO-[CH_2CH_2O]_n-H \longrightarrow$$

$$R-COO-[CH_2CH_2]_n-COR + HO-[CH_2CH_2O]_n-H$$

As carboxylic esters, fatty acid ethoxylates are sensitive to hydrolysis.

Ethoxylates of fatty acid amides are obtained not by ethoxylation of amides but by alkaline- catalyzed ethoxylation of fatty acid monoethanolamides or diethanolamides, which are obtained from the reaction of fatty acids or their methyl esters with ethanolamine or diethanolamine, which themselves are valuable products:

$$RCO-NH-CH_2CH_2OH$$

$$RCO-N(CH_2CH_2OH)_2$$

In the ethoxylation of primary amines, in the presence of basic catalysts, only one hydrogen atom bonded to nitrogen reacts, and the initially formed *N*-alkylethanolamine reacts further with ethylene oxide at the hydroxyl group, with the retention of the secondary amino group. Amines doubly ethoxylated on the nitrogen atom are obtained if the amines are first converted to the *N*-alkyldiethanolamine under proton catalysis, for which purpose small amounts of water are generally sufficient, and this diethanolamine is then ethoxylated further with alkaline catalysis.

Properties. Ethoxylates are described according to the state of aggregation (liquid, pasty, waxy, solid) and color (iodine no. < 2), and the density (ca. 1 g/cm^3), refractive index, and viscosity are specified as physical data. Characteristic data also include the cloud point (according to DIN 53 917) and the hydroxyl value. The content of active substance is generally given as 100 %, despite the fact that ethoxylates contain amounts of polydiols that increase with increasing degree of ethoxylation. An industrial lauryl alcohol ethoxylate containing 5 mol of EO/mol contains, e.g., ca. 0.5 %, an ethoxylate with 15 mol EO/mol contains 1.0 %, and one with 30 mol EO/mol contains 3.0 % of polydiol.

Storage and Dispatch. Ethoxylates are stored and transported in stainless steel or plastic vessels. Tank wagons and storage tanks for higher ethoxylated products that are solid at ambient temperature must be thermally insulated and heatable.

When ethoxylates are dissolved or diluted with water the possibility of gel formation in specific concentration ranges must be borne in mind.

CAS Numbers of some important ethoxylates are listed below. Irrespective of the degree of ethoxylation, ethoxylates with identical hydrophobic groups have the same CAS numbers.

Hydrophobic starting material	CAS number
100 % linear C_{10}-prim. alcohol	[26183-52-8]
100 % linear C_{10}/C_{12}-prim. alcohol	[66455-15-0]
100 % linear C_{12}-prim. alcohol	[9002-92-0]
100 % linear C_{12}/C_{14}-prim. alcohol	[68439-50-9]
100 % linear $C_{12}/C_{14}/C_{16}/C_{18}$-alcohol	[68213-23-0]
100 % linear C_{16}/C_{18}-prim. alcohol	[68439-49-6]

Producers. Fatty alcohol ethoxylates are produced in Europe, e. g., by Akzo, Albright & Wilson, Amerchol Europe, Auschem, BASF, Berol Nobel, Chem-Y, Croda, Harcros, Henkel, Hoechst, Hüls, ICI, Kolb, Pulcra, Rewo, Rhône-Poulenc, Seppic, Shell, Stepan, Witco, and Zschimmer & Schwarz; in North America, e. g., by Amerchol, BASF, Chemax, Croda, Exxon, Hart, Henkel/Emery, Hoechst Celanese, ICI Americas, Lonza, Olin, Procter & Gamble, Rhône-Poulenc Surfactant, Sandoz, Shell, Sherex, Stepan, Texaco, Union Carbide, Vista, and Witco; in Japan by Dai-Ichi, Nikko Chemicals, Nippon Nyukazai, Nippon Oil & Fat, Sanyo Chemical, and Takemoto Oil & Fat; in Australia by ICI; and in Taiwan by Sino-Japan Chemical and Taiwan Surfactant.

Alkylphenol ethoxylates are produced in Europe by Akzo, Auschem, BASF, Berol Nobel, Chem-Y, Dow, Harcros, Hefti, Hoechst, Hüls, ICI, Kolb, Pulcra, Stepan, Witco, and Union Carbide; in North America by Chemax, Clough Chemical, Exxon, Hart, Henkel/Emery, Hoechst Celanese, Norman/Fox, Rhône-Poulenc Surfactant, Sandoz, Stepan, Texaco, Union Carbide, and Witco; in Japan by Dai-Ichi, Kao, Lion, Marubeni Oil, Nippon Nyukazai, Nippon Oil & Fat, Sanyo Chemical, and Toho Chemical Industry; in Australia by ICI; and in Taiwan by Sino-Japan Chemical and Taiwan Surfactant.

Fatty acid ethoxylates are produced in Europe by BASF, Croda, Fina Oleochemicals, Harcros, Hefti, Henkel, Hüls, ICI, Stepan, Witco, and Zschimmer & Schwarz; in North America by Chemax, Emkay, Hart, Henkel, Hodag Chemical, ICI Americas, Lipo Chemicals, Lonza, PPG/Mazer, Rhône-Poulenc Surfactant, and Reilly-Whiteman; in Japan by Dai-Ichi, Kao, Nikko Chemicals, Nippon Nyukazai, Nippon Oil & Fat, and Toho Chemical Industry; in Australia by ICI; in Taiwan by Sino-Japan Chemical and Taiwan Surfactant; and in Israel by Zohar.

Special ethoxylated fatty esters and oils are also produced by companies such as Auschem, Croda, ICI, Th. Goldschmidt and Westbrook Lanolin in Europe, and Heterene Chemical, ICI Americas, Lonza, Rhône-Poulenc Surfactants, and Sherex in the United States.

Ethoxylated amines and/or fatty acid amides are produced in Europe by Albright & Wilson, Akzo, BASF, Berol Nobel, Harcros, Henkel, Hoechst, Hüls, Rewo, Rhône-Poulenc, and Zschimmer & Schwarz; in the United States by Akzo, Chemax, Ethox Chemicals, Hart, Henkel, Heterene Chemical, Karlshanns, PPG/Mazer, Rhône-Poulenc Surfactant, Sandoz, Sherex, Union Carbide and Witco; in Japan by Dai-Ichi, Kao, Nippon Nyukazai, Nippon Oil & Fats, and Sanyo; in Australia by ICI; and in Taiwan by Taiwan Surfactant and Sino-Japan Chemical.

7.3. Terminally Blocked Ethoxylates [109], [110]

By substituting the hydrogen atom of the terminal hydroxyl group of an ethoxylate by hydrophobic residues such as benzyl, butyl, or methyl groups, terminally blocked ethoxylates are obtained that are chemically more resistant, especially in alkaline media, than the corresponding ethoxylates with a free hydroxyl group. Since blocked ethoxylates also foam less in aqueous solution than their starting ethoxylates, they have a certain value in (alkaline) cleaning processes involving strong mechanical action.

The addition of higher alkylene oxides, in particular propylene oxide, may also be regarded as a terminal blocking:

However, since such products also contain free hydroxyl groups they are no more stable than their starting ethoxylates against alkalis, but in aqueous solution foam less than the pure ethoxylates. Due to the blocking of the terminal hydroxyl groups by hydrophobic residues such ethoxylates to some extent lose their surfactant character, and become less water-soluble and less amphiphilic. This is already noticeable in propoxylated products, the propoxy group itself being hydrophobic. This property can be utilized to enlarge a hydrophobic residue before ethoxylation by addition of propylene oxide. Finally, alkoxylation can be performed with mixtures of ethylene oxide and propylene oxide and various effects can be achieved by appropriately choosing the ratio of the two epoxides, by alternating the order of addition, etc.

7.4. Fatty Acid Esters of Polyhydroxy Compounds

Polyhydroxy compounds such as glycerol, diglycerol, polyglycerol, erythritol, pentaerythritol, xylitol, sorbitol, mannitol, sucrose, and other glucosides that are partially esterified with fatty acids have surface-active properties. The hydrophilicity (HLB value) of such esters can be increased and matched to the desired application by ethoxylating the unesterified hydroxyl groups. Esters of glycerol, sorbitol, and sucrose are discussed hereinafter by way of example, as are the so- called alkyl polyglucosides, which have recently attracted increased attention.

Fatty Acid Esters of Glycerol [111]. Disproportionating transesterification of fats and oils, the fatty acid triesters of glycerol (triglycerides), with glycerol in the presence of acid, but preferably alkaline catalysts, yields, depending on the glycerol excess, equilibrium reaction mixtures containing 35 – 60 % of monoglycerides, 35 –50 % of diglycerides, 1 – 20 % of triglycerides, 1 – 10 % of fatty acids and their alkali metal salts, and 1 – 10 % of glycerol after ca. 1 h at 200 –250 °C. Such so- called mono-diglycerides, which can also be obtained by direct reaction of free fatty acids with glycerol under acid catalysis, are marketed as mixtures. They are insoluble in water, and when they contain alkali metal salts of fatty acids, they are self-emulsifying. The fatty acids that are used are predominantly from the tallow fat range (palmitic and stearic acids). The above-mentioned mixtures are generally marketed under the name “monoglycerides”, e.g., “glycerol monostearates” (GMS).

High- concentration monoglycerides are obtained from the mixtures by molecular distillation. They consist mainly of α-glycerides, and contain less than 10 % of β-glycerides:

Since they crystallize in fine platelets, they impart a pearl gloss to pasty liquid detergents and cleansing agents.

Glycerides are widely used as emulsifiers in foods and cosmetics, as they are physiologically harmless. Characteristic data of some commercial products are listed in Table 14.

Table 14. Typical data of some industrial glycerides

	Glycerol monostearate	Glycerol mono/distearate	Glycerol mono/distearate, self-emulsifying	Glycerol monolaurate
CAS no.	[61789-09-1]	[68308-54-3]	[68308-54-3] [593-29-3]	[27215-38-9]

The enzymatically catalyzed synthesis of glycerides has not yet become industrially important [112].

Anionic surfactants having properties similar to those of the ether sulfates are obtained by sulfating monoglycerides and diglycerides [113].

Producers of glycerides include Akzo, Croda, Fina Oleochemicals, Gatte-Fosse, Hefti, Henkel, Hüls, ICI, Quest, Rewo, and Th. Goldschmidt in Europe; Goldschmidt Chemical, Henkel, Hodag, Hoechst-Celanese, Humko, Inolex, Karlshamns, Lonza, PPG/Mazer, and Witco in North America; Kao, Nikko Chemicals, Nippon Oil & Fats, and Toho in Japan; Taiwan Surfactant and Sino-Japan Chemical in Taiwan; and Zohar in Israel.

Fatty Acid Esters of Sorbitol [114]. Sorbitol can be converted to monoesters or polyesters by reaction with fatty acid chlorides under mild conditions in the presence of pyridine. The esterification is performed industrially with the free fatty acids or their methyl esters at elevated temperature; sorbitol readily undergoes dehydration to sorbitan, which can lose a further molecule of water to give isosorbitol, especially in the presence of acid catalysts:

Esterification is generally carried out at 200 –250 °C after the addition of small amounts of alkali, e.g., 0.1 % sodium hydroxide; depending on the molar ratio of the starting materials, fatty acid monoesters, diesters, or triesters of sorbitan are obtained. First marketed by Atlas Powder, these are known as “Span” types. They are water-insoluble products having low HLB values that are liquid at ambient temperature or melt below 100 °C. Ethoxylation of the Span types yields products having better water solubility and higher HLB values, namely the “Tweens”, which are waxy to solid products.

Spans and Tweens are dispatched in plastic containers, plastic- coated cardboard containers, or bags.

Producers of sorbitan esters include Akzo, Auschem, Croda, Hefti, Henkel, and ICI in Europe; Chemax, Croda, Henkel/Emery, Hodag, ICI Americas, Karlshamns, Lipo Chemical, Lonza, Norman/Fox, PPG/Mazer, Stepan, and Witco in North America; Kao, Nikko Chemicals, Nippon Nyukazai, Nippon Oil & Fats, Sanyo, and Toho in Japan; and Sino-Japan Chemical and Taiwan Surfactant in Taiwan.

Fatty Acid Esters of Sucrose [115], [116]. As a plentifully available natural raw material, sucrose is a suitable parent substance for the hydrophilic group of surfactants. Surfactants based on sucrose, especially their fatty acid esters, are nontoxic, do not irritate the skin, and are fully biodegradable. However, they have not hitherto gained wide acceptance industrially due to a certain instability of the sucrose glycoside bond, and the insolubility of sucrose in conventional organic solvents, which makes reactions involving sucrose more difficult. Fatty acid esters of sucrose are prepared by alkaline- catalyzed reaction with 1 – 2 mol of fatty acid methyl ester per mole of sucrose, the methanol being distilled off under vacuum. The temperature should not exceed 100 °C. Dimethylformamide or dimethyl sulfoxide, both highly toxic substances, are used as solvents and must be removed completely from the reaction product, which is laborious since sucrose esters are temperature sensitive and must not be heated too strongly.

Producers of sucrose esters include Croda, Gattefosse, and ICI in Europe; Amerchol, Croda, and Union Carbide in the United States; and Dai-Ichi in Japan.

Alkyl Polyglucosides [117-120]. Acetal-bonded glucosides mixed with oligoglucosides are obtained as a randomly distributed mixture of homologues by acetalation of glucose with fatty alcohols; the average number of glucose units per molecule being between 1 and 3, depending on the reaction parameters. Strictly speaking the products should be called alkyl oligoglucosides, though the incorrect term alkyl polyglucosides (APG) has persisted.

Alkyl polyglucosides are waxy, soft to glassy-solid, and colored yellow due to impurities. They are generally extremely soluble in water and are handled as 50 % aqueous solutions. The HLB values lie above 10, and can be varied in the range 11 – 15 by changing the length of the hydrophobic group and the degree of glucosidation. The surface tension of aqueous solutions is ca. 30 mN/m and the interfacial tension toward hydrocarbons 1 mN/m. Alkyl polyglucosides are moderate foaming agents and outstanding emulsifiers. They are suitable for washing textiles and hard surfaces, particularly in combination with other anionic and nonionic surfactants, with which they give synergistic effects. Alkyl polyglucosides decompose on heating; their aqueous solutions are stable in the pH range 3 –13. They are nontoxic, only slightly irritating to the skin, and biodegrade rapidly.

Alkyl polyglucosides can be prepared by direct reaction of anhydrous glucose with fatty alcohols. In another method, in which also aqueous glucose solution can be used, the latter is first reacted with butanol to form butyl glucoside, which is then reacted in a second stage with fatty alcohol to form the fatty alkyl oligoglucoside. Butanol and excess fatty alcohol are distilled off. Strong acids such as sulfuric acid are used as catalysts in both methods.

The alkyl polyglucoside thus obtained as a melt is dissolved in water and bleached with hydrogen peroxide.

CAS Numbers. C_8/C_{10}-Fatty alkyl polyglucoside [128664-36-8], C_{12}/C_{14}-fatty alkyl polyglucoside [136797-44-9].

Producers include Henkel in the United States, Kao in Japan, Seppic in France, and BASF, Henkel, and Hüls in Germany.

7.5. Amine Oxides [121], [122]

Reaction of tertiary amines such as fatty alkyldimethylamine or fatty amines doubly ethoxylated at the nitrogen atom with hydrogen peroxide yields amine oxides:

Surfactant amine oxides such as lauryldimethylamine oxide are insensitive to water hardness. They disperse lime soaps, foam satisfactorily and are mild to the skin. They are therefore widely used as constituents of dishwasher detergents, shampoos, and soaps. Amine oxides in neutral aqueous solution should be regarded as nonionic surfactants. They are protonated in acid solution and thus represent the transition to cationic surfactants.

CAS Numbers. Lauryldimethylamine oxide [1643-20-5]; Stearyldimethylamine oxide [2571-88-2]; Coco fatty alkyldimethylamine oxide [61788-90-7].

Producers of amine oxides include Akzo, Albright & Wilson, Ceca, Croda, Pulcra, Rewo, and Th. Goldschmidt in Europe; Clough, Ethyl, Goldschmidt Chemical, Henkel, McIntyre, PPG/Mazer, Rhône-Poulenc Surfactant, Sherex, Sher Chemicals, Stepan, and Witco in the United States; Nippon Oil & Fats in Japan; and Taiwan Surfactant in Taiwan.

[Top of Page]

8. Cationic Surfactants [123-125]

Surfactants whose hydrophilic group is a cation are termed cationic surfactants. The cationic structure may already be present in the surfactant molecule, as in the case of quaternary ammonium or phosphonium salts, or may be formed only in aqueous solution, as, for example, in ethoxylated fatty amines. In acidic solution, nonionic surfactants can adopt a cationic character due to protonation at a heteroatom; examples are fatty amine oxides and even ethoxylates, whose ether groups can form oxonium structures. However, strictly speaking only those surfactants that do not require protonation to become cationic are regarded as cationic surfactants.

The most important cationic surfactants are the quaternary nitrogen compounds: tetraalkylammonium salts, *N*,*N*-dialkylimidazolinium compounds, and *N*-alkylpyridinium salts. The positive electrical charge of the hydrophilic moiety confers on cationic surfactants properties that open up areas of application for which anionic and nonionic surfactants are unsuitable or less suitable. Important uses of these cationic surfactants are as microbicides, herbicides, corrosion inhibitors, oxidation inhibitors, adhesives, finishing and sizing agents, water repellents, fabric softeners, flotation aids, dispersants, levelling agents, etc.

Other cationic surfactants, e.g., the quaternary phosphonium salts or tertiary sulfonium salts are less important industrially, although they are very useful as phase-transfer catalysts in synthesis [126].

8.1. Quaternary Ammonium Compounds

Quaternary ammonium compounds are obtained by alkylating tertiary amines. At least one of the alkyl residues must be a relatively long alkyl group. In general, tertiary amines having one or two long alkyl residues are used as starting compounds (⟶ Amines, Aliphatic), to which are added shorter alkyl groups in the form of methyl chloride, ethyl chloride or bromide, or dimethyl sulfate. The corresponding ammonium chlorides, ammonium bromides, or ammonium methyl sulfates are then obtained. The addition requires a polar solvent (e.g., alcohol); in the case of alkyl chlorides, which are mainly used for the alkylation, temperatures of 50 – 100 °C and reaction times of several hours are required. The process can be simplified by carrying out the reaction under pressure in excess alkylating agent (e.g., methyl chloride as solvent). The product is isolated by releasing the pressure and evaporating unreacted alkyl chloride [127].

Benzyl chloride reacts very readily as alkylating agent; the disinfectant Zephirol is obtained by addition to dimethyldodecylamine:

Another method of quaternizing tertiary amines, as well as ethoxylated fatty amines, is the reaction with ethylene oxide and water in the absence of a catalyst:

For special applications quaternary compounds can also be obtained from fatty acid derivatives such as the amides of diamines or esters of triethanolamine:

$RCONHCH_2CH_2N(CH_3)_2$

$RCOOCH_2CH_2N(CH_2CH_2OH)_2$

A further group of amines that is suitable for quaternization is obtained by hydrogenating substituted propionitriles, which are obtained by addition of fatty alcohols or fatty amines to acrylonitrile:

$ROCH_2CH_2CH_2NH_2$ and $RNHCH_2CH_2CH_2NH_2$

Distearyldimethylammonium chloride (DSDMAC) or, more correctly, since the long alkyl residues are tallow fat alkyl residues, ditallow alkyl dimethyl ammonium chloride (DTDMAC), was for a long time the most important component in fabric softeners. Since it proved to be relatively toxic to water-borne organisms [128], it has been replaced by less toxic ammonium compounds, which contain ester group as cleavage sites which lead to rapid breakdown of the compounds in water. These are the so- called esterquats obtained from fatty acid, triethanolamine or *N*-methyldiethanolamine, and dimethyl sulfate [129], [130]:

and the diesterquats obtainable from epoxypropyltrimethylammonium chloride and fatty acids [131]:

Typical data of some simple quaternary ammonium chlorides that are stored and transported in the form of aqueous or aqueous-alcoholic solution in stainless steel or plastic drums are listed in Table 15.

Table 15. Typical data of some industrial quaternary ammonium compounds

Producers of quaternary ammonium compounds include Akzo, BASF, Bayer, Berol, Ceca, Croda, Fina Oleochemicals, Hoechst, Hüls, ICI, Pulcra, Rewo, Rhône-Poulenc, Stepan, and Witco in Europe; Akzo, Emkay, Henkel, Hoechst, Humko, ICI, Karlshamns, Rhône-Poulenc, Sherex, and Witco in North America; Kao, Marubishi Oil, Sanyo Chemical, Takemoto Oil, Tokai Seiyu, and Yoshimura Oil in Japan; and Taiwan Surfactant in Taiwan.

8.2. Imidazoline Derivatives

Condensation of fatty acids with ethylenediamine or substituted ethylenediamine yields substituted imidazolines, e.g.:

Such compounds are strongly cationic in acidic solution, but undergo slow hydrolysis [132]:

True cationic surfactants are obtained by alkylating imidazoline derivatives, mainly with chloromethane:

Such surfactants have properties similar to those of acyclic quaternary ammonium salts; they are dermatologically extremely compatible, are antiseptic, and are used as wetting agents, dispersants and cleansing agents, including bodycare products.

An imidazoline derivative obtained by reacting 1 mol of *N*-aminoethylethylenediamine with 2 mol of fatty acid, and quaternized with dimethyl sulfate, is an important fabric softener [86088-85-9] [133]:

[Top of Page]

9. Amphoteric Surfactants [134-136]

Amphoteric surfactants can be classified as ampholytes and betaines. Ampholytes are compounds having at least one active proton, the best-known example being aminocarboxylic acids, which at the isoelectric point exist as inner salts, at low pH values as cationic species, and at higher pH values as anionic species:

Betaines have no mobile protons and are true amphoteric ions which assume a cationic nature in strongly acid media:

Ampholytes are of minor industrial importance, largely on account of the marked dependence of their properties on pH. Ampholytes are prepared by reacting fatty amines with chloroacetic acid and sodium hydroxide, or by alkaline- catalyzed addition of acrylic acid to fatty amines:

Betaines are prepared by reacting a tertiary amine with chloroacetic acid and sodium hydroxide:

or

The sulfobetaines are now of only minor importance. Of the various ways of preparing sulfobetaines, the elegant synthesis from amines, alkyl chloride, and sodium hydrogensulfite is mentioned here [137]:

$$RN(CH_3)_2 + CH_2{=}CH_2CH_2Cl \longrightarrow [RN(CH_3)_2CH_2CH{=}CH_2]^+\ Cl^-$$

$$[RN(CH_3)_2CH_2CH{=}CH_2]^+\ Cl^- + NaHSO_3 \xrightarrow{-\,NaCl} RN(CH_3)_2CH_2CH_2CH_2SO_3^-$$

Nowadays only true betaines are of economic importance, especially acid amide betaines and the betaines derived from imidazolines:

The latter, which are prepared in aqueous solution, probably exist in the open- chain form [138].

Betaines are insensitive to the water hardness and pH value of industrial water, are only slightly toxic, are compatible with the skin and mucous membranes, and have antimicrobial properties. They have good washing and foaming performance and are highly compatible with other classes of surfactants, and are therefore ideally suited for use in bodycare products.

Lecithin or phosphatidylcholine, a naturally occurring phospholipid also belongs to the class of betaines [139], [140]:

Producers of ampholytes and betaines include Akzo, Albright & Wilson, Auschem, Croda, Harcros, Henkel, Hüls, Manro, Pulcra, Rewo, Rhône-Poulenc, Seppic, Stepan, Th. Goldschmidt, Union Carbide, and Zschimmer & Schwarz in Europe; Clough, Goldschmidt Chemicals, Henkel, Inolex, McIntyre, Mona, PPG/Mazer, Rhône-Poulenc Surfactant, Sher Chemicals, Sherex, Stepan, and Witco in the United States; Lion, Nippon Oil & Fats, Sanyo, and Toho in Japan; Taiwan Surfactant in Taiwan; and Zohar in Israel.

[Top of Page]

10. Surfactants with Heteroatoms in the Hydrophobic Group

10.1. Block Copolymers of Propylene Oxide and Ethylene Oxide [141], [142]

The incorporation of propoxy groups in a surfactant increases its hydrophobicity. Hydrophobic parent substances of any desired molecular mass can be prepared by addition of propylene oxide to a low molecular mass starter molecule. Propoxylation is performed analogously to ethoxylation, with alkaline catalysts at 120 –180 °C under a slight excess pressure:

Suitable starter molecules are monofunctional or polyfunctional protic substances, for example, methanol, ethanol, propanol, or higher alcohols; diols such as butanediol; and triols such as gylcerol. Propylene glycol itself is also a suitable diol, and ethylenediamine is a suitable tetrafunctional starter molecule. Subsequent ethoxylation of hydrophobic parent substances obtained in this way yields nonionic surfactants, which can be described as block copolymers of propylene oxide and ethylene oxide. When using polyfunctional starters, branching occurs at the starter molecule. Derivatives of propylene glycol and ethylenediamine, first introduced by Wyandotte under the trade names of Pluronics and Tetronics, are now the most important surfactants of this type:

As the structural formulas indicate, a wide range of block copolymers can be synthesized. The products are not uniform, and a homologue distribution range exists for each propoxylate chain and for each ethoxylate chain. Mean molecular masses of 1000 – 5000 are preferred in the case of hydrophobic propoxylate parent substances. Ethoxylation can also be varied over a wide range; depending on the desired application, HLB value and cloud point, between 10 and 80 wt % of ethylene oxide is added.

The products are liquids, pastes, or waxy solids, depending on the molecular mass. They are water-soluble above a content of about 25 wt % of bound ethylene oxide. They are also relatively stable to alkalis and acids.

Their outstanding property is the lack of foaming ability of their aqueous solutions; the propylene oxide – ethylene oxide addition products also suppress the foam of strongly foaming solutions. The block copolymers are therefore preferably used as wetting and cleaning agents in processes involving high mechanical stress and in high-speed cleaning machines. They are also used as demulsifiers and dispersants. However, their unsatisfactory biodegradability prevents their widespread use.

Producers include BASF, Berol, Nobel, Dow, Harcros, Hoechst, Hüls, ICI, and Rhône-Poulenc in Europe; BASF, Hart, Henkel, ICI Americas, Norman/Fox, Olin, and PPG/Mazer in North America; Dai-Ichi and Nippon Oil & Fats in Japan; ICI in Australia; and Sino-Japan Chemical in Taiwan.

10.2. Silicone-Based Surfactants [143-148]

Silicone-based surfactants are mainly derived from methylsilicones (polydimethylsiloxanes, ⟶ Silicones – Polydimethylsiloxanes ⟶ Silicones ⟶ Silicones). They lower the surface tension of water to a greater degree than hydrocarbon-based surfactants, and in this respect are inferior only to fluorosurfactants. In their molecular structure silicone-based surfac-tants resemble surfactants containing polypropylene glycol as hydrophobic parent substance, since the hydrophobic silicone group also has a random molecular mass distribution. The following basic structures (linear, comb, and branched) occur, where A denotes hydrophilic groups:

Polydimethylsiloxanes are prepared by selective hydrolysis of dimethyldichlorosilane:

The terminal chlorine atoms may be substituted in the presence of bases by polyethylene glycol residues, resulting in nonionic surfactants of the ethoxylate type.

A special feature of silicone chemistry is the “equilibration” of the polymers, in which molecular mass distribution and distribution of the individual siloxane building blocks can be brought into a reproducible equilibrium by redistribution of the siloxane bonds under acid catalysis. The linear, comb, and branched silicones are formed in this way.

Equilibration enables substituents to be incorporated in the silicone molecule. The silicon – hydrogen bonds of silanes can add to an aliphatic double bond in the presence of hexachloroplatinic acid:

The group R can carry functional groups. By addition of allyl alcohol, for example, hydroxyl- containing dichlorosilanes can be produced, which are converted by selective hydrolysis to poly(methylhydroxypropyl)siloxane, which can be equilibrated with a polydimethylsiloxane. The hydroxyl groups introduced in this way can be reacted further, for example by sulfation to give sulfuric hemi-esters, which yield anionic surfactants.

The choice of the siloxane building blocks, selective hydrolysis, and equilibration enable a wide variety of silicone surfactants to be synthesized. The polysiloxane residues of most silicone surfactants have a polymeric character, in contrast to the previously discussed hydrocarbon-based surfactants. Polar and nonpolar groups alternate in the polymer chain, similar to the polypropylene glycol derivatives or the polypeptides. In the polysiloxanes discussed here, the alternating groups are oxygen bridges and dimethylsilyl groups. The oxygen bridges can interact weakly with water, with the result that a polydimethylsiloxane residue forms a layer on the water surface, with oxygen atoms oriented towards the aqueous phase. The same is true of pure, nonfunctionalized polydimethylsiloxanes, which have a surfactant character because they have a lower surface tension due to the weak mutual cohesive forces of the siloxane residues.

The layer structure of the polysiloxane boundary films, on the other hand, renders these films a certain strength. Polysiloxanes modified with polyethers are therefore important as integrated constituents of polyurethane foams, in which they act as foam stabilizers. The stability of films of silicone surfactants in aqueous foams makes them useful as additives to aqueous fire-extinguishing agents. Although silicone surfactants form stable foams, they are able to destroy foams of hydrocarbon-based surfactants, which they displace from the surface because of their higher surface activity.

The polysiloxane skeleton is biologically persistent, and is broken down only slowly in the environment by hydrolysis. However, polydimethylsiloxanes are physiologically harmless. Silicone-based surfactants are used in a wide range of special applications, for example, in skincare and haircare preparations [145]; in the production of fibers and textiles [146]; as wetting agents, dispersants, and flow- control agents in the production of paints and coatings [147]; as mold release agents in plastics processing; and as defoaming agents, emulsifiers, demulsifiers, and water repellents.

Producers. Silicone-based surfactants are produced in Europe by Hoechst and Th. Goldschmidt; in the United States by Dow Corning, Goldschmidt Chemical, Rhône-Poulenc Surfactant, Troy Chemical, and Union Carbide; and in Japan by Tosho and Yoshimura Oil Chemical.

10.3. Fluorosurfactants [149-151]

The fluorosurfactants used nowadays can be regarded as analogues of surfactants containing aliphatic hydrocarbon groups, in which the hydrogen atoms have been wholly or partly replaced by fluorine atoms. The extreme hydrophobicity of fluorinated hydrocarbons means, however, that amphiphilic fluorine compounds with substantially shorter hydrophobic residues than their aliphatic analogs are already surface-active. Whereas a marked interfacial activity in salts of aliphatic carboxylic acids is observed starting with 8 – 9 carbon atoms in the hydrophobic group, perfluorobutyric acid and its salts are already considerably surface-active. The very low cohesive forces between the fluorinated alkyl groups result in extremely low surface tensions of fluorosurfactants. Surface tensions ≤ 20 mN/m can be achieved only with fluorosurfactants. Fluorosurfactants have very low CMCs and are hence already active at very low concentrations, which to some extent compensates for their high cost. Fluorosurfactants have high chemical and thermal stability, and accordingly are used for special applications (high-temperature processes, electroplating techniques). They diffuse rapidly in aqueous solution, and are therefore also suitable for high-speed industrial processes.

Perfluoroalkane carboxylic or perfluoroalkanesulfonic acids are prepared by electrochemical fluorination of the corresponding carboxylic acids or sulfonic acids. Telomerization of perfluoroethylene with, for example, pentafluoroiodoethane as starter molecule yields homologous perfluoro-1-iodoalkanes, which can be converted to carboxylic acids, sulfonic acids, phosphonic acids, or amines. Perfluoroalkenes, possibly branched, are obtained by anionically catalyzed oligomerization of tetrafluoroethylene; a fluorine atom located at the double bond can be electrophilically replaced, in the presence of a base, by alcohol, phenol, ethylene glycol, or olgioethylene glycol to give nonionic surfactants of the ethoxylate type.

Fluorosurfactants are used as wetting, emulsifying, and flow- control agents; as absorption agents for imparting water-repellent and soil-repellent properties to textiles, leather, and paper; in coating photocopying paper; as mold release agents for plastics; and as additives in fire-extinguishing agents.

Producers of fluorosurfactants include Hoechst in Europe and 3 M and Du Pont in the United States.

[Top of Page]

11. Analysis [152-157]

Surface-active substances are identified qualitatively by the fact that their solutions foam and wet fibers or solid surfaces more quickly than pure water, and also by the reduction in surface tension of water, which is recognized by the rapid sinking of a small thin metal or PVC plate carefully laid on the surface of the water, which would otherwise be held on the surface in the absence of surfactants. These test methods are not unambiguous, however, not all surface-active substances should be regarded as surfactants.

11.1. Identification of Surfactants

A number of group-specific detection reactions are known for identifying different types of surfactants, which, however, have become less important with improvements in

instrumental analysis. The property of anionic and cationic surfactants of forming sparingly soluble salts in water can be used as a quick aid; an anionic surfactant, for example a sulfonate, can be precipitated with a cationic surfactant, for example a quaternary ammonium salt, and vice versa. Anionic surfactants produce a precipitate on addition of aluminum acetate, and soaps are converted to water-insoluble fatty acids on acidification. Nonionic surfactants of the ethoxylate type and cationic surfactants form precipitates sparingly soluble in water with phosphotungstic and phosphomolybdic acids, potassium hexacyanoferrate, and Dragendorff's reagent (barium bismuth iodide). Amphoteric surfactants also form precipitates with phosphotungstic and phosphomolybdic acids; generally, they are sparingly soluble at their isoelectric point.

The modern method of choice for identifying surfactants is IR spectroscopy, for which many reference spectra exist. This technique has been refined to such an extent that amounts of less than 1 µg can be measured. UV spectroscopy allows identification of surfactants containing aromatic groups.

Mass spectroscopy, which is generally employed in combination with gas chromatography and high-pressure liquid chromatography, has also become a valuable aid in surfactant analysis, especially after the introduction of soft ionization methods such as direct chemical ionization (DCI), field desorption (FD), and fast atom bombardment, which can also be applied to nonvaporizable substances. Although mass spectroscopy is complex and therefore unsuitable for routine investigations, NMR spectroscopy, especially ^{1}H NMR, has become an extremely useful tool in surfactant analysis, for example, in identifying hydrophobic hydrocarbon parent substances and in determining the number of added ethylene oxide or propylene oxide molecules in alkoxylates.

Gas chromatography is now an important method in surfactant analysis. Substances of low volatility are often modified chemically for GC analysis. Ethoxylates, for example, are determined as trimethylsilyl ethers; homologues containing up to seven ethylene oxide units per mole can be determined in this way. Fatty acids and sulfonic acids are subjected to GC in the form of their methyl esters. Gas chromatography and mass spectroscopy are suitable for identifying hydrophobic residues of surfactants after specific pyrolytic decomposition. With concentrated phosphoric acid at 215 °C the structurally unchanged alkylbenzene is obtained from the corresponding alkylbenzenesulfonate, while alkanes shortened by the hydrophilic group are obtained from alkyl sulfates, fatty acid esters, and fatty acid amides. Alkanesulfonates and α-sulfocarboxylic esters produce nonuniform fragments in this type of pyrolysis. In the pyrolysis of alkylbenzenesulfonate or alkanesulfonate in a KOH – NaOH melt at 290 °C, the parent hydrocarbons are obtained as alkylphenols or alkenes. Quaternary ammonium compounds are subjected to Hofmann degradation with potassium hydroxide or sodium hydroxide, in which alkene and tertiary amines are formed. Decomposition and GC separation can be coupled on-line (pyrolysis – gas chromatography). Decomposition is often performed as Curie point pyrolysis to ensure reproducible fragmentation under controlled conditions.

Iodoalkane, ethylene, and iodine are formed when ethoxylates are reacted with boiling 58 % hydroiodic acid:

$$\mathrm{RO-[CH_2CH_2O]_n-H} + (2n+1)\mathrm{HI} \rightarrow \mathrm{RI} + n\mathrm{CH_2{=}CH_2} + n\mathrm{I_2} + (n+1)\mathrm{H_2O}$$

The parent substances and their simple derivatives obtained from the reaction can also be identified by gas chromatography or mass spectrometry.

The decomposition of ethoxylates with hydroiodic acid is also utilized in the wet chemical determination of the degree of ethoxylation *n* of an ethoxylate; the iodine released is titrated with thiosulfate solution.

A modification of this Zeisel cleavage converts the ethoxy groups to ethyliodide and propoxy groups to propyliodide which again can be determined by GC.

11.2. Isolation and Separation

Surfactants often exist as a mixture of different types of surfactant or mixed with nonsurfactant components. A number of methods are available for separating and specifically isolating individual surfactants and for removing byproducts.

Extraction. Nonpolar constituents (neutral oil) can be extracted with petroleum ether from neutral or alkaline-adjusted aqueous or aqueous-alcoholic solutions of anionic surfactants. If the solution is acidified, fatty acids also pass into the petroleum ether phase.

Surfactant sulfonic acids are extracted from aqueous hydrochloric acid sulutions with diethyl ether. Short- chain alkylbenzenesulfonic acids, disulfonic acids, etc., remain in the aqueous phase, from which they can be extracted with butanol.

Polyglycols (polydiols) can be extracted from solutions of ethoxylates in ethyl acetate by using aqueous sodium chloride solution. Ethoxylates are extracted from aqueous solution by chloroform after saturating the solution with sodium chloride.

Blowing Out. Blowing out is a nonspecific method for isolating traces of all surface-active substances from aqueous solutions. A stream of nitrogen loaded with ethyl acetate vapor is passed through a frit into the solution. Surfactants are adsorbed on the surfaces of the nitrogen bubbles and transported upwardly, where they are absorbed in an ethyl acetate phase covering the aqueous solution. This method is used in trace analysis of surfactants, especially in effluents and wastewaters.

Adsorption. Surfactants can be separated by adsorption on aluminum oxide, activated charcoal, polymer resins, or silica gel. Using solvents of increasing polarity it is possible, by column chromatography, to separate nonionic surfactants from anionic surfactants, and nonionic surfactants of different HLB value from one another. Reverse-phase cartridges have been used to recover traces of surfactant from aqueous solution.

Ion exchangers are being used increasingly in surfactant separation and analysis, and a quantitative analysis procedure has been proposed [152]. Three ion-exchange columns are connected in series: a strongly acidic cation exchanger in the H^+ form, in which quaternary ammonium compounds, betaines, and imidazoline derivatives are retained from ethanolic solution; a strongly basic anion exchanger in the Cl^- form, which retains sulfonates and sulfates; and a strongly basic anion exchanger in the OH^- form, where fatty acids and aminocarboxylic acids are retained. The nonionic surfactants appear in the eluate. The surfactants retained in the columns are eluted with aqueous ethanolic hydrochloric acid or 2 % aqueous isopropanolic sodium hydroxide and then separated further.

A procedure for separating surfactants from heavy-duty detergents that do not contain any cationic surfactants is as follows [158]: the ethanol-soluble material is redissolved in a mixture of isopropanol and water and subjected to a double ion exchange (cation exchanger and macroporous anion exchanger). The eluate contains the nonionic surfactant. The anion exchanger is then charged with ethanol saturated with carbon dioxide, whereby the soaps are eluted. The hydrotropic compounds (e.g., cumenesulfonate) are then isolated with a solution of 1 N ammonium bicarbonate in 80 parts of water and 20 parts of isopropanol, and finally the sulfonates and sulfates are isolated with 0.3 N ammonium bicarbonate solution in 60 parts of water and 40 parts of isopropanol.

The two separation processes described above demonstrate the numerous possibilities provided by ion exchangers in surfactant analysis.

Chromatographic Methods. Besides gas chromatography (GC), thin-layer chromatography (TLC) is an important method [159], which has the advantage of being able to identify directly individual surfactants even in mixtures.

High-performance liquid chromatography (HPLC) and gradient gel-permeation chromatography (GPC) are being increasingly used. Not only can homologous and analogous compounds be separated in this way, but trace constituents can be also detected.

Supercritical fluid chromatography (SCF) has recently become important especially for higher ethoxylates [160], and capillary electrophoresis, which is suitable for separating ionic compounds, is also occasionally used.

11.3. Quantitative Determination

The afore-described methods of identifying and isolating surfactants are often also suitable for their quantitative determination. HCLP has become a powerful tool for quantitative analysis in the last few years. In chromatographic methods, quantiative determination is performed by calibration with reference substances. For extracts or eluates available in larger amounts, this is performed gravimetrically after evaporation or after precipitation with a specific reagent. Also, direct or indirect photometric determination in solution using calibration curves is often employed. The term indirect photometric determination refers to the photometric determination of a substance containing a chromophor that forms a salt, an addition compound or a complex of defined composition with the surfactant and which is quantitatively determined after reaction with the surfactant.

Anionic and cationic surfactants can also be determined by volumetric analysis if the molecular mass is known or assumed. A solution of a surfactant having an opposite electrical charge to that of the surfactant ion is used for titration. Anionic and cationic surfactants generally form sparingly soluble salts in water; the titration can be performed turbidimetrically as a precipitation titration. The determination of the endpoint can also be achieved potentiometrically with tenside-selective electrodes, e. g., by means of a graphite electrode coated with poly(vinyl chloride) [161].

Two-phase Epton titration is universally employed, especially for the volumetric determination of sulfonates and sulfates. The titration of the anionic surfactant is performed in two mutually immiscible solvents (water and trichloromethane) with a cationic surfactant such as *n*- cetylpyridinium chloride or Hyamine 1622. The water-insoluble cation and anion surfactant salt formed in the titration dissolves in the chloroform phase. The end point is indicated by dyes or dye mixtures which form salts with the surfactants and pass from one phase to the other at the end point.

Modified Epton Titration (CIA Method). The anionic surfactant is titrated in the two-phase system water –trichloromethane with Hyamine 1622, a cationic surfactant. The indicator is a mixture of the cationic dye dimidium bromide and the anionic dye Disulfin Blue VN. The anionic surfactant forms a salt with the cationic dye, which dissolves in trichloromethane to give a pinkish-red color. At the end point the Hyamine cation displaces the dimidium cation from the salt and thus from the trichloromethane, the red coloration migrating to the aqueous phase. Excess Hyamine forms a salt with the dye Disulfin Blue, which dissolves in trichloromethane to give a blue color. At the end point the color of the trichloromethane phase thus changes from red through colorless to blue.

Longwell – Maniece Methylene Blue Method. Sulfonate and sulfate surfactants form salts with the cationic dye methylene blue that are insoluble in water but soluble in trichloromethane. Since methylene blue, which is added as its hydrochloride, is practically insoluble in trichloromethane, when the aqueous and trichloromethane phases are mixed the dye passes into the trichloromethane phase only in an amount equivalent to the quantity of anionic species. The surfactant concentration in the trichloromethane extract can then be determined accurately by photometric determination at 650 nm.

The Longwell – Maniece methylene blue method can be combined with the blowing out process for trace analysis of residual surfactants in biodegradation experiments and of surfactants in effluents and wastewaters. As little as 20 µg of alkylbenzenesulfonate can be determined.

The anionic surfactant determined with this method is termed methylene blue active substance (MBAS).

Determination of Cationic Surfactants with Disulfin Blue (Kunkel Method). This method is based on the formation of a trichloromethane soluble salt of a cationic surfactant with the anionic dye Disulfin Blue. A solution of the cationic surfactant in trichloromethane is thoroughly mixed with the aqueous ethanolic solution of the dye. After separating the phases the trichloromethane phase is evaporated, and the residue dissolved in methanol. This solution is determined photometrically at 628 nm. Substance-specific calibration curves are used for evaluation. This method can be used in combination with the blowing out process for trace analysis; 10 µg of cationic surfactant can be determined. The cationic surfactant determined using this method is termed Disulfin Blue substance (DSBS).

Ethoxylates are determined not in a twophase titration, but indirectly via a precipitation reaction.

Determination of Ethoxylates with Dragendorff's Reagent (Wickbold Method). With modified Dragendorff's reagent (barium chloride/potassium tetraiodobismuthate (III) in glacial acetic acid) ethoxylates containing ≥ 6 mol of ethylene oxide per mole form sparingly soluble precipitates in water. The precipitate is filtered, washed with glacial acetic acid, dissolved in ammonium tartrate solution, and acidified with sulfuric acid. The bismuth present in solution is titrated with ethylenediamine tetraacetate solution with xylenol orange as indicator. To calculate the amount of ethoxylate, substance-specific calibration factors are required, which can also be calculated if the mean molecular mass of the surfactant is known sufficiently accurately.

In another type of titration, especially suitable for trace analysis, the precipitate is dissolved in ammonium tartrate and titrated with pyrrolidine dithiocarbamate solution; the end point is determined potentiographically. Using this method allows as little as 50 µg of nonylphenol ethoxylate (10 mol EO/mol) to be detected.

The nonionic surfactants determined by this method are termed bismuth-active substances (BiAS).

The four methods of quantitative surfactant determination outlined above presuppose a knowledge of the mean molecular mass of the investigated surfactant. As calibration or reference substance tetrapropylenebenzenesulfonate is used for anionic surfactants, nonylphenol ethoxylate containing 10 mol of ethylene oxide per mole for nonionic surfactants, and dodecyldimethylbenzylammonium chloride for cationic surfactants.

11.4. Unspecific Additive Parameters

The titrimetric methods discussed above for the analytical, in particular quantitative determination of surfactants are group-specific and are associated with the amphiphilic nature of the surfactants. The methods fail as soon as polar, hydrophilic groups are introduced into the hydrophobic residue, for example, by enzymatic attack. However, especially in investigations on the biodegradation of surfactants, not only is the loss of surface-active properties of interest but also their further degradation, i.e., enzymatic oxidation to water, carbon dioxide, sulfate, nitrate, etc. It is thus important to determine the intermediate products, the metabolites. However, due to the large number of possible metabolites, which in many cases occur only in very small amounts, the effort and cost involved in their individual determination is disproportionately large. To obtain some information about the overall biodegradability of surfactants, attempts were already made early on to determine substance-unspecific additive parameters that are generally employable for characterizing the pollution of rivers and waters by organic substances (BOD and COD values) and, more recently, the TOC and DOC values.

BOD Value. In the measurement of the biological oxygen demand (BOD) the biological decomposition (biodegradation) of a surfactant is simulated by adding it to a mineral nutrient salt solution that has been inocculated with a broad-spectrum bacterial culture. The solutions are incubated at 20 °C in closed flasks; the oxygen content in the initially air-saturated solution is determined after 5, 15, and 30 d. The oxygen consumption calculated from these values is expressed as a percentage BOD 5, BOD 15, or BOD 30 value, relative to the amount of oxygen required for total oxidation of the test substance.

COD Value. In the determination of the chemical oxygen demand (COD) the organic water-borne constituents are characterized by chemical oxidation with potassium dichromate in sulfuric acid solution in the presence of silver ions. The COD values depend largely on the chemical structure. For example, the readily biodegradable compound acetic acid is scarcely attacked by chromic acid. However, in the case of more complex compounds such as surfactants, correlations exist between COD and BOD values for groups of similar surfactants. Thus the quickly and easily performed COD determination can be used to give an indication of the BOD value. The COD is expressed as a percentage of the amount of oxygen calculated for total oxidation.

TOC Value. The total organic carbon (TOC) in an aqueous solution is the most suitable quantity for expressing the extent of mineralization of a substance in aqueous, bacterially infected solution. The TOC value is determined by combustion of the organic substances to carbon dioxide in a hot reactor through which a stream of air is passed and into which a measured water sample is injected. The amount carbon dioxide in the off-gas from the reactor is determined quantitatively by IR spectroscopy and is used to calculate the carbon content in the sample. With the development of analytical equipment that determines carbon automatically in the mg/L range, the TOC method has become an important analytical tool. The degree of biodegradation of a substance can be specified simply as a percentage by determining the TOC value before and after the degradation experiment if the investigated substance is the sole source of carbon for the microorganisms. Since inorganic carbon in the form of dissolved carbon dioxide or carbonate may also be present in the investigated solutions, the sample is acidified before combustion and the inorganic carbon is expelled as carbon dioxide. The TOC analysis can however also be carried out in two parallel determinations, one of which, performed at a high temperature, determines the total dissolved carbon, while the other, performed at a low temperature, determines only the inorganically bound carbon by acidification and sparging with air. The TOC value is then the difference between the total carbon and inorganically bound carbon.

DOC Value. If the carbon determination is carried out by the TOC method after filtering the sample, then the DOC value (dissolved organic carbon) is obtained.

[Top of Page]

12. Utility Evaluation of Surfactants

Besides the purely analytical methods a large number of utility evaluation methods, in some cases standardized, have been introduced for the characterization and quality control of surfactants. A list of the relevant ISO and DIN regulations is given below:

ISO 304:	Surface Active Agents — Determination of Surface Tension by Drawing Up Liquid Films
ISO 607:	Surface Active Agents and Detergents — Methods of Sample Division
ISO 696:	Surface Active Agents — Measurements of Foaming Power — Modified Ross – Miles Method
ISO 697:	Surface Active Agents — Washing Powders — Determination of Apparent Density — Method by Measuring the Mass of a Given Volume
ISO 1063:	Surface Active Agents — Determination of Stability in Hard Water
ISO 1064:	Surface Active Agents — Determination of Apparent Density of Pastes on Filling
ISO 1065:	Non-Ionic Surface active agents obtained from Ethylene Oxide — Determination of Cloud Temperature (cloud point)
ISO 2131:	Surface Active Agents — Simplified Classification
ISO 2174:	Surface Active Agents — Preparation of Water with Known Calcium Hardness
ISO 2267:	Surface Active Agents — Evaluation of Certain Effects of Laundering — Methods of Preparation and Use of Unsoiled Cotton Control Cloth
ISO 2456:	Surface Active Agents — Water Used as a Solvent for Tests — Specification and Test Methods
ISO 4198:	Surface Active Agents — Detergents for Hand Dishwashing — Guide for Comparative Testing of Performance
ISO 4311:	Anionic and Non-Ionic Surface Active Agents — Determination of the Critical Micellization Concentration — Method by Measuring Surface Tension with a Plate, Stirrup or Ring
ISO 4312:	Surface Active Agents — Evaluation of Certain Effects of Laundering — Methods of Analysis and Test for Unsoiled Cotton Control Cloth
ISO 4316:	Surface Active Agents — Determination of pH of Aqueous Solutions — Potentiometric Method
ISO 4317:	Surface Active Agents — Determination of Water Content — Karl Fischer Method
ISO 4319:	Surface Active Agents — Detergents for Washing Fabrics — Guide for Comparative Testing of Performance
ISO 4320:	Non-Ionic Surface Active Agents — Determination of Cloud Point Index — Volumetric Method
ISO 4324:	Surface Active Agents — Powder and Granules — Measurement of the Angle of Repose
ISO 6387:	Surface Active Agents — Determination of the Power to Disperse Calcium Soap — Acidimetric Method (Modified Schoenfeldt

	Method)
ISO 6388:	Surface Active Agents — Determination of Flow Properties Using a Rotational Viscometer
ISO 6836:	Surface Active Agents — Mercerizing Agents — Evaluation of the Activity of Wetting Products for Mercerization by Determination of the Shrinkage Rate of Cotton
ISO 6837:	Surface Active Agents — Water Dispersing Power in Dry Cleaning Solvents
ISO 6839:	Anionic Surface Active Agents — Determination of Solubility in Water
ISO 6840:	Cationic Surface Agents (Hydrochlorides and Hydrobromides) — Determination of Critical Micellization Concentration — Method by Measurement of Counter Ion Activity
ISO 6889:	Surface Active Agents — Determination of Interfacial Tension by Drawing Up Liquid Film
ISO 7535:	Surface Active Agents — Detergents for Domestic Machine Dishwashing — Guide for Comparative Testing of Performance
ISO 8022:	Surface Active Agents — Determination of Wetting Power by Immersion
ISO 8212:	Soaps and Detergents — Techniques of Sampling During Manufacture
ISO 9101:	Surface Active Agents — Determination of Interfacial Tension — Drop Volume Method
DIN 59 900:	Terms and Definitions
DIN 53 901:	Determination of the Wetting Ability of Surfactant Solutions by Measuring the Time required for a Small Piece of Cotton Cloth Added to the Solution to Sink
DIN 53 902:	Determinations of the Foaming Power of Surfactant Solutions by the Perforated Disk impact Method or the Ross – Miles Method
DIN 53 903:	Determination of the Power to Disperse Calcium Soaps for Pure Calcium Water Hardness
DIN 53 904:	Determination of the Ability to Wash Out Lubricants from Textiles
DIN 53 905:	Determination of the Hard Water Resistance of Surfactants
DIN 53 908:	Determination of the Dispersive Power of Surfactants with Respect to Dyes
DIN 53 910:	Preparation of Hard Water having Adjusted Calcium Hardness
DIN 53 911:	Sampling of Powders and Preparation of Size-Reduced Average Samples
DIN 53 912:	Determination of the Bulk Density of Powders and Granules
DIN 53 913:	Determination of the Filling Density of Pastes, Ointments, and Gelatinous Materials
DIN 53 914:	Determination of the Surface Tension
DIN 53 916:	Determination of the Flowability of Powders and Granules
DIN 53 917:	Determination of the Cloud Point of Ethoxylates
DIN 53 918:	Determination of the Krafft Point and Solubility of Ionic Surfactants
DIN 53 921:	Measurement of the Flow Properties by means of a Rotational Viscometer
DIN 53 988:	Examination of the Action of Levelling Agents in Vat Dyes
DIN 53 989:	Determination of the Turbidity Titration Number
DIN 53 990:	Principles of the Comparative Examination of Utility Properties of Detergents for Washing Textiles
DIN 53 993:	Determination of Interfacial Tension by the Stirrup or Ring Method.

Many methods used for testing the detergency and cleansing power of surfactants and surfactant formulations in their solutions have not hitherto been standardized. To evaluate the detergent power in textiles reproducibly soiled test fabrics are washed in the presence of the test substance in washing machines or washing simulators. After the test fabric has been dried and ironed its degree of whiteness is measured as remission of white light (e.g., in a Zeiss Elrepho apparatus), and compared with the remission values of the unwashed soiled test fabric, and of the unsoiled clean test fabric.

To test the cleaning effect on hard surfaces the latter are dirtied with colored greases and treated with solutions of the test substances. The degree of removal of the colorant from the surface is a measure of the cleaning effect. In the plate-rinsing test greasy plates are washed in succession in the solution of the product to be tested. The detergent power is determined on the basis of the number of plates that can be cleaned until the detergent solution no longer contains any foam and the dirt that has been washed off collects visibly on the surface of the rinsing water.

An important property of surfactants and their formulations, mainly for aesthetic reasons, is their color. Slightly colored or even colorless surfactants are preferred. Among the various methods for determining the color, those predominate in which the yellow and brown shades that mainly occur in surfactants as also in other organic substances are determined. In the iodine color value (DIN 6162, standard method C IV 4a of the Deutsche Gesellschaft für Fettwissenschaft, DGF) the color of a solution of the test substance is compared optically with the color of solutions of iodine of various concentrations in aqueous potassium iodide solution and specified as mg iodine/100 mL. In the Hazen color index (APHA, ASTM D-1209–69; A.O.C.S. Td 1b-64) solutions of platinum and cobalt salts of different concentrations are used as reference solution. In the Klett color index the extinction ($E = \log I_0/I$) of blue light of wavelength 420 –430 nm passing through a solution of the test substance is directly measured photometrically and multiplied by the factor 1000; turbidities are also expressed as color indices in this method.

The Lovibond and Gardner color indices provide a differentiated expression of the color of a solution. In the Lovibond color index (standard method C IV 4b of the DGF) the color of a beam of light passing through the solution is compared in the optical field of a colorimeter with a second beam of light passed through yellow, red, and blue filters of adjustable thickness. The color index is specified by three figures, corresponding to the thicknesses of the three filters. The measurement of the Gardner color index (DIN – ISO 4630; A.O.C.S. Td 1a-64), standard method C IV c of the DGF) is based on the same principle, though the reference colors are already standardized as mixed colors and are specified by means of progressively numbered colored glasses.

The above methods have proved their worth in practice even though they have the disadvantage that they are based on a subjective and comparative perception or, as in the case of the Klett index, are restricted to measurements within a narrow spectral range.

Although an objective determination of the color shade in the CIE color triangle is possible by measuring the overall visible spectrum and conversion to tristimulus values, this method is laborious. A simplified method based on the latter for the colorimetric characterization of transparent liquids is proposed in [162].

[Top of Page]

13. Uses [1-3], [6]

The largest proportion of surfactants is used in *detergents* and *cleansing agents* for domestic and industrial use (⟶ Dry Cleaning, ⟶ Cleansing Agents, ⟶ Laundry Detergents, ⟶ Soaps) [4], [163-166]. In universal laundry detergents mainly combinations of alkylbenzenesulfonate, fatty alcohol ethoxylate, and soaps, in addition to other components, are used. In modern washing machines the soap serves primarily not as a surfactant and cleansing agent, but as a foam regulator. Nowadays it is increasingly being replaced by, for example, the more effective silicone oils. Occasionally, tallow fat alkyl sulfate is used to partly or completely replace alkylbenzenesulfonate. Specialty detergents are similar in surfactant composition as regards the components; instead of tallow fat alkyl sulfates, coconut oil alkyl sulfates and coconut oil ether sulfates, which dissolve better in the cold are preferred.

In fabric softeners, cationic surfactants are employed. On account of their good crystallizability sulfosuccinates and olefinsulfonates are employed besides alkylbenzenesulfonate and ethoxylates in foam cleaning agents and dry cleaning agents. Besides dodecylbenzenesulfonates, alkylbenzenes with shorter alkyl chains, C_{14} – C_{17} alkanesulfonates, C_{12} – C_{14} olefinsulfonates, and fatty alcohol ether sulfates are preferably added to liquid rinsing agents and cleansing agents since they produce highly concentrated, clear solutions. Due to their better dermatological compatibility betaines are added to domestic washing up liquids. Alternatively a proportion of the anionic surfactants is replaced by nonionic surfactants such as fatty alcohol ethoxylates or alkyl polyglucosides.

In the industrial cleansing sector particular importance is placed on the degreasing and emulsifying ability, foam behavior, electrolyte compatibility, and chemical stability of the products. Besides alkylbenzenesulfonates, alkanesulfonates, fatty alcohol ethoxylates, alkylphenol ethoxylates, and fatty amine ethoxylates, phosphate esters and low-foam nonionic surfactants such as propylene oxide/ethylene oxide adducts or terminally blocked ethoxylates are also important here.

Mild surfactants that are gentle to the skin play an important role in bodycare products, and especially in cosmetic cleansing agents (⟶ Skin Cosmetics – Surfactants) [167-169]. Such surfactants include ether sulfates and ether carboxylates, sulfosuccinic esters of fatty alcohol polyglycol ethers, protein – fatty acid condensates and the related sarcosinates and taurides, isethionates, as well as ampholytes and betaines, amine oxides, fatty acid polyglycol and sorbitan esters, and alkyl polyglucosides.

A broad field of application of surfactants is the *textile industry*, historically the oldest sector, with its numerous processes such as washing, cleaning, lubricating, sizing, fulling, bleaching, mercerizing, carbonizing, and finishing (⟶ Textile Auxiliaries) [170], [171]. Almost exclusively nonionic surfactants are used for washing wool. Cotton is washed alkaline, for which purpose nonionic and anionic surfactants are suitable (alkylbenzenesulfonates, alkyl sulfates and sulfosuccinates). In lubricating, a process in which the slip of the fibers is improved, mainly fatty acid and fatty alcohol ethoxylates are used. Sulfonates, sulfates, or ethoxylates are used for desizing, in which the mutual adhesion of the fibers is overcome. Soaps or ethoxylates are used in fulling. Bleaching auxiliaries include alkyl sulfates, alkylbenzenesulfonates, and alkylphenol ethoxylates. Mercerization, the treatment of cotton with a concentrated lye, requires wetting agents such as alkanesulfonates, alkyl sulfates, or alkyl phosphates. Alkanesulfonates or alkyl sulfates are also used in carbonizing, i.e., treatment with sulfuric acid. Softening, which improves the handle of textiles, is largely carried out with cationic surfactants.

Surfactants are also required as emulsifiers, dispersants, levelling agents, and swelling agents in textile dyeing (⟶ Textile Dyeing; ⟶ Disperse Systems and Dispersants – Terminology).

The *leather industry* uses nonionic and cationic surfactants as wetting and cleansing agents. Leather oils, which are used to grease leather, contain alkane sulfonates or alkyl sulfates. Cationic surfactants are used in the aftertreatment of leather to make it supple and water-repellent.

Surfactants have a wide range of application as *emulsifiers* (⟶ Emulsions) [172-175] and *dispersants* (⟶ Disperse Systems and Dispersants). The foods industry uses mainly natural substances such as fatty acid salts, glycerides, and fatty acid esters of lactic acid, tartaric acid, and sorbitol (⟶ Foods, 3. Food Additives – Stabilizers ⟶ Foods, 3. Food Additives – Emulsifiers).

Mainly fatty alcohol ethoxylates and fatty alcohol sulfates, fatty acid ethoxylates, and fatty acid esters of glycerol and sorbitol are used in *pharmacy*, where attention must be paid to pharmacological and toxicological innocuousness (⟶ Pharmaceutical Dosage Forms – Quality Assurance) [176].

Emulsifiers are added to *crop-protection* and pest- control agents since the active substances are often only sparingly soluble in water. Emulsifiers widely used here include the sodium, calcium, and diethanolammonium salts of alkylbenzenesulfonic acids, ethoxylates of alkylphenols and condensed phenols, and fatty acid esters of polyglycols, glycerol, and sorbitol. Short- chain alkylbenzene sulfonates and alkylnaphthalene sulfonates are used as wetting agents.

Emulsifiers are required in numerous operations involved in *petroleum production.* The drilling muds used in large amounts for cooling and rinsing in drilling technology contain, for example, alkylbenzenesulfonate or lignin sulfonate to suspend the solids. Lignin sulfonate and naphthalenesulfonate are used as a cement additive in the construction of boreholes. Demulsifiers, e.g., condensation products of propylene oxide and ethylene oxide, ethoxylates of alcohols, fatty acids, alkylphenols, and condensed phenols, are indispensable in working up the oil, which is initially obtained as a water – oil emul-sion.

Emulsions of water and mineral oil are widely used in *metalworking* and machining. They act as lubricants and coolants in drilling, cutting, rolling, and drawing. Preferred emulsifiers include the heavy metal salts of fatty acids and naphtenic acids, as well as salts of phosphoric esters or carboxymethylated ethoxylates.

Quenching oils for steel hardening contain ethoxylates of fatty alcohols or alkylphenols. Emulsions prepared with ethoxylates or sulfonates are suitable as mold release agents in casting and founding. Alkaline-adjusted mineral oil emulsions, prepared using ethoxylates based on alkylphenols or fatty amines, are used as cleansing agents. Emulsions prepared with phosphates, quaternary ammonium salts or ethoxylated fatty acid ethanolamides are used as anticorrosion agents.

In the *mineral oil industry* emulsifiers play a significant role as additives for cleaning carburetors and as flow enhancers and corrosion inhibitors.

Emulsifiers used in petroleum exploration, production and processing [177], and for oil slick control are mainly nonionic dispersants or demulsifiers [178]. A potential use of ethoxylates or modified ethoxylates is for transporting heavy oils and bitumen as low-water emulsions [179], or coal as concentrated coal – water slurries[180].

Almost exclusively cationic surfactants, more specifically amine oxides, fatty amine salts and imidazoline salts, are used for bitumen application in *road construction* work.

In the *cement industry* alkylnaphthalenesulfonates are used as wetting agents, phenol – formaldehyde – sodium bisulfite adducts or lignin sulfonates are used as flow enhancers, and ethoxylates are used to form air pores.

The production of numerous plastics by *emulsion polymerization* is only possible by using emulsifiers (soaps, alkylbenzenesulfonates, alkanesulfonates, alkyl sulfates, primary and quaternary ammonium salts, pyridinium salts, fatty alcohol ethoxylates and alkylphenol ethoxylates, glycerides, sorbitol esters, etc.). Other uses of surfactants in the plastics industry include stabilization of polymer dispersions, production of foamed plastics, mold release agents, and production of microcapsules.

In the production of *paints and coatings* a broad range of emulsifiers is required to disperse pigments and emulsify oils and resins, and to act as flow- control and thickening agents. Suitable dispersants include ethoxylates of alkylphenols, fatty alcohols and fatty acids, sulfated oils and naphthenates; ethoxylates and sulfonates are used as emulsifiers.

Adhesives contain mainly nonionic surfactants, which emulsify constituents of the adhesive, and ensure rapid wetting of the surfaces to be bonded.

In *pulp and paper* production, ethoxylates, alkanesulfonates, alkylnaphthalenesulfonates are used as wetting agents to remove resinous constituents. Various ethoxylates and sulfonates as well as cationic surfactants are used in paper sizing and finishing.

Surfactants are used in *electroplating* to clean metal surfaces and also to accelerate hydrogen evolution at the cathode. Fatty alcohol ethoxylates and sulfates are often used, and in some cases also alkylbenzenesulfonates. Fluorosurfactants are particularly advantageous in electroplating due to their chemical stability.

Fire-extinguishing foams are produced by adding alkyl or alkyl ether sulfates and fatty acid esters to water. Rapid wetting of the material to be extinguished can be achieved by using fluoro surfactants.

Alkylphenol ethoxylates, sorbitol esters, glycerides, alkylbenzenesulfonates, and sulfosuccinic esters are used in the *photographic industry* to produce light-sensitive emulsions.

An increasingly important use of surfactants is *ore flotation* (⟶ Flotation) [181-183].

The applications listed above by no means exhaust the possible uses of surfactants. Further applications are described in [183-186]. A few applications of minor industrial importance are: the catalysis of chemical reactions in micelles and vesicles [17], [187]; phase-transfer catalysis [188]; extractions in multiple emulsions on liquid membranes [189]; ion-pair extraction [190] and coacervate extraction [191], which is preferably used in the separation of biological materials from aqueous solutions; and admicellar chromatography [192], in which micelles adsorbed on a solid surface act as carrier phase.

Finally, the detailed study of microemulsions has opened up a broad application potential for the latter [193-195].

[Top of Page]

14. Economic Aspects

World production of surfactants is ca. 15× 10^6 t/a. Of this, soaps account for ca. 8×10^6 t/a; in many countries they are still the most important surfactant for everyday use. After soaps, the alkylbenzenesulfonates are quantitatively the most important class of surfactants, accounting for ca. 2×10^6 t/a.

Surfactants are mainly marketed as constituents of finished products, together with nonsurfactant components. In many cases their specific consumption cannot be determined exactly on account of lack of knowledge of their content in commercial products, even when consumption data exist for products themselves. Also, most market estimates are limited to specific application sectors. There are therefore no accurate data on the total consumption. Estimated production figures in 10^3 t/a for some surfactants in 1990 were as follows:

Linear alkylbenzenesulfonates	1700
Branched alkylbenzenesulfonates	300
Lignin sulfonates	600
Fatty alcohol ether sulfates	400
Fatty alcohol sulfates	300
Petroleum sulfonates	200
Alkanesulfonates	100
Fatty alcohol ethoxylates	700
Alkylphenol ethoxylates	500
Fatty acid esters	300
Fatty acid alkanolamides	100
Quaternary ammonium compounds	300
Other amine derivatives	100

Surfactant consumption (in 10^3 t/a) according to fields of application in the United States, Japan, and Western Europe in 1982 broke down as follows [196]:

Washing and cleaning	1900
Cosmetics and pharmacy	300
Textiles and fibers	200
Leather and furs	50
Colorants, coatings, and plastics	200
Cellulose and paper	100
Mining, flotation, and oil production	300
Metalworking	130
Building and construction	50
Crop protection and pest control	100
Foods	200
Miscellaneous	400

15. Toxicology and Environmental Aspects

15.1. Introduction

Surfactants are used in many areas of human activity, in the home and in commerce, in agriculture, and in industry. Their effects on living organisms are therefore particularly important, even in cases where products, when used according to the instructions, do not come into direct contact with higher life forms. A large number of surfactants come into direct contact with human skin, as constituents of detergents and cleansing agents; their accidental oral ingestion, even if only as residues on washed dishes, therefore cannot be ruled out. Surfactants used as auxiliaries in foods and beverages are therefore subject to legal provisions that require them to be absolutely harmless. The special attention that is nowadays paid to the possible harmful effects of chemicals has meant that some surfactants intended for use in the foods sector are not permitted for use as such in all countries. A characteristic feature or surfactants permitted for use in the foodstuffs sector is that they are overwhelmingly natural products or are obtained from natural products by slight chemical modification. They are mainly derived from glycerides, fatty acids, lactic, tartaric, and citric acids, sugar, and sorbitol.

Irrespective of their intended use, product safety — including environmental protection — is of major importance for all surfactants. The fate and effect of surfactants in rivers and waters are of particular importance in environmental risk assessment, since a large proportion of surfactants is discharged after use into effluent and sewage and ultimately flows into rivers, lakes, and oceans. Here, the degradation of surfactants by microorganisms in natural waters and in sewage plants, which ultimately leads to their complete mineralization is particularly important.

15.2. Toxicology [197-199]

The majority of surfactants now in use — alkylbenzenesulfonates, alkyl ether sulfates, alkyl sulfates, alkanesulfonates, olefinsulfonates, alkyl polyglycol ethers, and nonylphenol polyglycol ethers — are nontoxic or have only a slight acute or chronic toxicity. Also, no toxic effects of the metabolites of these surfactants have been detected in mammals.

The oral LD_{50} values of both anionic and nonionic surfactants is generally in the range from several hundred to several thousand milligrams per kilogram of body weight (comparable to sodium chloride). Betaines, which are used in particular in body cleansing preparations, are nontoxic. The quaternary ammonium compounds, which are known to be bactericidal and fungicidal, exhibit a range of behavior. Whereas dialkyldimethylammonium chlorides used as fabric softeners have LD_{50} values of ca. 5 g/kg body weight and are nontoxic, alkylbenzyldimethylammonium chloride used as a disinfectant has a fairly low LD_{50} value of 0.35 g/kg.

There are few data on the toxicity of surfactants derived from polysiloxanes or fluoroalkanes. Methylpolysiloxanes are physiologically inert, but this is not necessarily the case for phenyl-substituted polysiloxanes.

Nothing is known of the carcinogenic, mutagenic, or teratogenic effects of surfactants.

There is no danger of acute lethal toxicity by resorption of surfactants through the skin or by inhalation. Surfactants can cause skin irritation and skin damage on prolonged action, since they destroy the water-lipid membrane that serves as the external protective layer of the skin, by dissolving individual constituents. The immediate results are swelling, drying, and chapping of the skin; prolonged action of surfactants can lead to eczematous changes in the skin, which recede when the source of irritation is removed.

There are a large number of standardized methods for testing irritation of the skin and mucous membranes. It is important to differentiate between tests under practically relevant conditions at realistic concentrations, and tests used to determine the potential hazard of pure substances, as required, for example, by the German Chemikaliengesetz (Chemicals Act). According to the latter most surfactants should be characterized as “irritant”, a few as “moderately toxic”, while strongly acidic or basic products, including a number of amine derivatives and ammonium salts, as “corrosive” [200]. Such effects detected at high concentration hardly ever occur if surfactants are used according to the instructions, either because such concentrations are not employed, or because the time the surfactant is in contact with the skin is too short to produce an irritant or indeed a corrosive effect.

Skin irritation generally increases in the sequence nonionic, amphoteric, anionic, cationic surfactants. Aromatic rings in the hydrophobic group increase the irritant action. Good wetting agents have a higher irritant potential than poor wetting agents. With anionic surfactants containing a linear alkyl group such as soaps, alkyl sulfates, and olefinsulfates, maximum skin irritation is found for an alkyl chain length of 12 carbon atoms. The incorporation of oligoglycol residues between hydrophobic and hydrophilic groups, as in fatty alcohol ether sulfates, fatty alcohol sulfosuccinates, or fatty alcohol carboxylates, reduces the irritant action of such anionic surfactants.

Nitrogen- containing surfactants irritate the skin less, and the action of sulfonates or sulfates is reduced by using their ammonium salts (e.g., triethanolammonium salts).

The above comments regarding skin irritation also apply to irritation of the mucous membranes, but the mucous membranes are much more sensitive than the skin.

Betaines and amine oxides are extremely weakly irritating to the skin; they reduce the irritant action of anionic surfactants.

On account of their compatibility with the skin and mucous membranes, betaines, fatty acid amidoalkylaminobetaines, amphoteric *N*-alkylamino acids, and fatty acid alkylolamidoether sulfates are playing an increasing role as constituents of body cleansing agents. Condensation products of fatty acids and protein degradation products (oligopeptides) have long been known to be particularly gentle to the skin and mucous membranes.

Allergies and sensitizations due to surfactants are uncommon. If they do occur, it should be checked whether they are caused by accompanying substances or impurities in the surfactants.

15.3. Biological Degradation [201-203]

Organic substances can be degraded aerobically and anaerobically by microorganisms in the presence of water. Since surfactants are discharged after use mainly into effluent and sewage and thus eventually into rivers and seas, their aerobic biodegradation is of primary interest, which is already reflected in Europe in a number of legislative measures

(⟶ Laundry Detergents – General Criteria for the Ecological Evaluation of Detergent Chemicals). In the determination of the biodegradability a distinction is made between the primary attack on the surfactant molecule and total degradation. Primary attack is the loss of interfacial activity due to a structural change in the surfactant molecule. Total degradation is the complete conversion of the surfactant into inorganic substances (e.g., sodium sulfate, carbon dioxide, water) and the incorporation of its constituents into the cellular material of microorganisms.

Primary attack, which has been shown to lead to total degradation, albeit after a long time, is easy to determine (in contrast to total degradation) by measuring analytically the residual surfactant in a degradation test. Intact anionic surfactants are detected as methylene blue-active substances (MBAS), nonionic surfactants as bismuth-active substance (BiAS), and cationic surfactants as DSBAS (see Section Quantitative Determination).

The investigation of the degradation pathways of a surfactant to total degradation is laborious and time- consuming, and up to now has been performed only on a few, industrially particularly important surfactants (e.g., linear alkylbenzene sulfonate; see below). To quickly obtain information on total degradation, additive parameters are nowadays preferably employed (see Section Unspecific Additive Parameters), which can readily be determined in degradation experiments.

15.3.1. *Methods for Determining Biological Degradation*

The test specifications recommended by the OECD have been adopted by the EC states as well as by some other countries. These are the static OECD screening test, which simulates the conditions of surface waters, and the continuous OECD confirmatory test in which the processes occurring in a sewage plant are approximated using activated sludge (⟶ Laundry Detergents – Environmental Exposure Assessment, ⟶ Laundry Detergents – Assessment of Environmental Effects) [204].

Whereas surfactant-specific analysis only provides information on primary attack, the introduction of the DOC method (dissolved organic carbon) provides further, but however only summary information, on the degradation of a surfactant. If the surfactant is the sole source of carbon in the test solution, then the determination of the organically bound carbon in the solution at the start and end of the experiment provides a direct measure of the degradation of the surfactant. The DOC method can be extended to the OECD confirmatory test if two units instead of one are operated, surfactant being added to the inflow of one unit but not to the other. A homogeneous composition of the bioceonosis in both batches is ensured by daily exchange of sludge between the parallel units. Entrainment of surfactant, which could influence the DOC values, is taken into account computationally in the evaluation of the results. Reliable balances and thus information on the degree of degradation of the surfactants can be obtained by this method by employing suitable technical and statistical measures [205].

Although it is complicated and costly, this so- called coupled units test has nowadays become a standard method (⟶ Laundry Detergents – Biodegradability Standard Test Methods). If the overflowing effluent in this continuously operated test is recycled up to fifty times and replenished with fresh surfactant, additional information is obtained on difficultly degradable catabolites or byproducts in the surfactant used (catabolites test) [206].

In addition to these methods a large number of other test methods are used, some of which have been adopted and numbered in the OECD Guidelines as ready, inherent, and simulation tests:

Ready Tests	
Die Away Test	301 A
Modified Sturm Test	301 B
Modified MITI (I) Test	301 C
Modified Closed Bottle Test	301 D
Modified OECD Screening Test	301 E
Inherent Tests	
Modified SCAS Test	302 A
(SCAS = Semicontinuous activated sludge)	
Modified Zahn – Wellens Test	302 B
Modified MITI (II) Test	302 C
Simulation Test	
Coupled Units Test	303 A
Inherent Biodegradability in Soil	304 A

Whereas most of the aforementioned methods determine the biodegradation via DOC analysis, in the closed bottle test the oxygen consumption is measured, while in the MITI and STURM tests the carbon dioxide evolution is measured. Information on widely used test methods is given in Table 16 [207]. In the ready tests such as the closed bottle or Sturm tests, besides information on the biodegradability of the substance information can also be obtained on the ready biodegradability, which applies if a degree of degradation of at least 70 % is achieved after a degree of degradation of 10 % is exceeded within 10 d (Fig. 22).

Table 16. Test methods for determining total degradation (mineralization)

Test method	Characteristics of the test	Analysis	Test duration, d	Degree of degradation to be regarded as degradable
Modified OECD screening test	static test (small amount of organisms)	DOC	28	> 70 %
Closed bottle test	static test (small amount of organisms)	O_2	28	> 60 %
Sturm test	static test (small amount of organisms)	CO_2	28	> 60 %
Zahn – Wellens test	static test (activated sludge)	DOC	28	> 70 %
Coupled units test	continuous test (simulation of a communal clarification plant)	DOC	≥ 30	> 70 %
Catabolites test	continuous test with recycling and replenishment of the purified effuent	DOC	≥ 30	the necessary degree of degradation depends on the carbon content of the test substance
ECETOC test	static test (digested sludge); anaerobic conditions	CH_4 and CO_2	≥ 30	not specified

Figure 22. Curves illustrating the DOC decrease of two readily biodegradable substances [207]

All the methods mentioned here refer to the aerobic biodegradation of surfactants. Since the surfactants used nowadays in consumer products undergo rapid aerobic degradation, their anaerobic degradation plays only a minor role in ecological considerations. Accordingly, at present there are still no validated methods for determining anaerobic degradation. Occasionally, the ECETOC test is used.

A further, very informative but complex and expensive method is the use of radioactively labelled (generally ^{14}C) material in a degradation experiment and identification of the radioactive end products.

A specialist report has summarized a large amount of data on biogradation and other ecologically relevant data concerning surfactants [208]; this information is reproduced in abbreviated and supplemented form in Table 17.

Table 17. Biodegradability and ecotoxicity of important surfactants [208], supplemented

15.3.2. *Biodegradation Mechanisms*

Surfactants whose hydrophobic group are derived from hydrocarbons can be oxidized enzymatically under aerobic conditions and thus biodegraded. Surfactants derived from hydrophobic parent substances such as perfluoroalkanes, poly(propylene glycols), or polydimethylsiloxanes are not biodegradable.

The enzymatic attack leading to biodegradation occurs in most surfactants at the hydrophobic group. For ionic surfactants the nature of the hydrophilic group has only a minor influence on the rate of degradation. High biodegradation rates have been found even for bactericidal quaternary ammonium compounds such as cetyltrimethylammonium bromide, benzyldodecyldimethylammonium chloride, and distearyldimethylammonium chloride. With nonionic surfactants of the ethoxylate type the degradation rate is influenced by the length of the poly(ethylene glycol) chain (i.e., by the degree of ethoxylation); with the same hydrophobic residue, the degradation rate decreases with increasing length of the poly(ethylene glycol) chain.

The constitution of the hydrophobic hydrocarbon group of a surfactant has a decisive influence on the degradation rate.

Branchings in an aliphatic group strongly decelerates degradation. Phenylidene groups between the aliphatic and hydrophilic groups can make degradation slower. Linear alkylbenzenesulfonates are degraded more slowly than alkanesulfonates and olefinsulfonates, and the latter more slowly than linear alkyl sulfates.

Natural fatty acids and their salts as well as some of their esters with glycerol, sorbitol or sugars are readily biodegradable, although in the case of the esters a decrease in the degradation rate is already observed, which can be explained by the need for a preceding hydrolysis. The enzymatic oxidative degradation of linear fatty acids takes place mainly by β-oxidation, in which the hydrocarbon chain is shortened each time by two carbon atoms.

Aerobic biodegradation of secondary alkanesulfonates probably begins with oxidative desulfonation; the resulting oxoalkanes are readily degraded.

In the case of internal sulfonates, alkylbenzenesulfonates, and alcohol ethoxylates, microbial degradation can be initiated by ω-oxidation, i.e., by oxidative attack on both terminal methyl groups. After introduction of the terminal carboxylate groups further degradation then proceeds as β-oxidation. In the degradation of alkylbenzenesulfonates sulfophenylalkanecarboxylic acids are formed as intermediates, while in the degradation of fatty alcohol ethoxylates polyglycol ethers of ω-hydroxyalkanecarboxylic acids are formed as intermediates.

The biodegradation of the industrially most important surfactant, alkylbenzenesulfonate (also named dodecylbenzenesulfonate since the mean number of carbon atoms in the alkyl group is 12) has been largely elucidated. The degradative pathway proceeds by ω-oxidation and subsequent β-oxidation, followed by ring opening. The sulfonate group remains bound to the carbon atom after opening of the aromatic ring. The homologous and isomeric species contained in the alkylbenzenesulfonate are attacked at various rates. According to the “distance principle”, the degradation rate increases with increasing distance of the terminal methyl group from the coupling site of the sulfophenyl group, or the length of the available unsubstituted alkyl chain. For example, 2-dodecylbenzenesulfonate is degraded more rapidly than 6-dodecylbenzenesulfonate, which in turn is degraded more quickly than 6-undecylbenzenesulfonate.

That ca. 70 % of the benzene nuclei in industrial alkylbenzenesulfonate are already degraded under the conditions of the OECD confirmatory test has been confirmed by examining the degradation of an alkylbenzenesulfonate labeled in the benzene nucleus with ^{14}C [209].

Tetrapropylenebenzenesulfonate is difficultly biodegradable on account of its highly branched alkyl group.

Nonionic surfactants of the ethoxylate type are also preferentially degraded starting from the hydrophobic group by enzymatic attack on a terminal methyl group. The degradation rate decreases sharply with increasing branching of the hydrophobic alkyl group. With simple branching, which occurs for example in the case of isomeric oxoalcohols, the distance principle applies to the degradation of ethoxylates as it does for linear alkylbenzene sulfonates, whereby the surfactant is degraded more quickly the longer a linear alkyl residue starting from a branching site is:

The biodegradation of linear ethoxylates proceeds by two different mechanisms that seems occur simultaneously:

1. The molecule is cleaved at the ether bridge between the alkyl group and the polyethylene glycol ether group, following which both fragments are degraded independently of one another
2. Microbial attack occurs simultaneously at both ends of the molecule, i.e., at the terminal methyl group of the alkyl chain and at the hydroxyl group of the poly(ethylene glycol) unit

The alkyl group of industrial alkylphenol ethoxylates are attacked microbially with difficulty on account of their high degree of branching. In this case the degradation proceeds from the polyglycol chain: The chain is shortened starting from the end of the free hydroxyl group, stepwise in each case by one ethylene glycol unit, glycolic acid presumably being formed as an intermediate:

Degradation becomes slower with decreasing length of the polyglycol chain. Since the hydrocarbon skeleton is also degraded with difficulty, the total mineralization of alkylphenol ethoxylates proceeds more slowly than the fast primary degradation.

15.3.3. *Toxicity of Surfactants and their Metabolites to Aquatic Organisms [210]*

The toxicity of surfactants to aquatic organisms can only be evaluated if the rate and completeness of their biodegradation is taken into account. Thus substances with high toxicity will generally not have any harmful effect on aquatic organisms if they are degraded sufficiently quickly.

The toxicity is tested on green algae (Chlorella), water fleas (Daphnia), fish (trout, orfe, goldfish), and mixed bacterial cultures. These trout and young orfe are particularly sensitive to surfactants; therefore, lethal and nonlethal concentrations for these fish are measured to provide preliminary information (screening). In Germany orfe are used for testing; the test method, in which the fish are exposed for 48 h to graduated concentrations of the surfactant in the ambient water, has been standardized. Nonlethal concentrations (48-h LC_0 in mg/L) of some common surfactants for orfe are listed below:

Sodium tetrapropylenebenzenesulfonate	8.0
Sodium dodecylbenzenesulfonate (linear)	2.3
Sodium alkanesulfonate (C_{14} – C_{17})	3.0
Sodium olefinsulfonate (C_{14} – C_{16})	2.0
Sodium tallow fat alcohol sulfate	6.0
Sodium tallow fat alkyl ether sulfate containing 3 EO	10.0
Nonylphenol polyglycol ether with 9 EO	5 – 6
Fatty alcohol polyglycol ether with 5 EO	1 – 2
Fatty alcohol polyglycol ether with 10 EO	2 – 3
Fatty alcohol polyglycol ether with 14 EO	3 – 4

Fish toxicity is strongly dependent on the structure of the surfactant, as exemplified by the structural isomers tetrapropylenebenzenesulfonate (branched side chain) and dodecylbenzenesulfonate (linear side chain). In general, fish toxicity increases with the effective length of the hydrophobic group; in anionic surfactants, branching and an internally located hydrophilic group reduce the toxicity. This is exemplified by the fish toxicity (LC_{50}) of alkylbenzenesulfonate isomers (for *Carassius auratus* [210]):

5-decylbenzenesulfonate	76
2-decylbenzenesulfonate	36
6-undecylbenzenesulfonate	46.5
2-undecylbenzenesulfonate	14.5
6-dodecylbenzenesulfonate	20.5
2-dodecylbenzenesulfonate	4.5
7-tridecylbenzenesulfonate	8.5
2-tridecylbenzenesulfonate	2.0

These toxicity data demonstrate clearly that the toxicity of surfactants cannot be considered separately from their biodegradation in natural waters, since the toxic isomers are degraded most rapidly, (distance principle) and accordingly reach the waters in far lower concentration, if at all, than the less toxic internal isomers.

Except for one striking exception, up to now nothing is known about the aquatic toxicity of catabolites produced in the biodegradation of surfactants. The exception are the isononylphenol ethoxylates, which, because of their marked degree of branching are degraded not from the alkyl residue but from the terminal hydroxyl group of the poly (ethylene glycol) chain, whereby the degradation rate decreases with decreasing number of ethylene oxide units in the poly(ethylene glycol) chain. The diethylene glycol and monoethylene glycol ethers that are formed as intermediates and degrade only slowly and exhibit, like the parent substance isononyl(or isooctyl)phenol, a pronounced toxicity to aquatic organisms, which is much higher than that of alkylphenol ethoxylate surfactants with degrees of ethoxylation of 5 and above [104].

Anionic and nonionic surfactants are generally nontoxic to bacteria. However, reference is made here to a remarkable connection between chemical structure and bacterial toxicity in the case of nonionic surfactants, which in particular cases may result in an inhibition of the biodegradation of some nonionic surfactants. The toxicity of ethoxylates increases sharply with decreasing length of the poly(ethylene glycol) chain (see Table 17). Some toxicity threshold values (TLV in mg/L) for *Pseudomonas* are given below:

Coconut oil fatty alcohol polyglycol ether with 10 EO	1000

Coconut oil fatty alcohol polyglycol ether with 2 EO	10
Stearyl alcohol polyglycol ether with 25 EO	10 000
Stearyl alcohol polyglycol ether with 10 EO	100
Stearyl alcohol polyglycol ether with 2 EO	10
Nonylphenol polyglycol ether with 10 EO	1 000
Nonylphenol polyglycol ether with 6 EO	500
Nonylphenol polyglycol ether with 4 EO	50

A number of quaternary ammonium compounds and betaines have a substantial bactericidal activity. However, if sufficiently diluted these compounds, too, are biodegraded if the chemical structure of the hydrophobic group allows enzymatic attack to occur.

15.4. Preservation of Surfactants [211], [212]

The biodegradation of surfactants occurs not only at high dilution in waters and rivers, but in the presence of water can already start in the production process, in storage and transportation vessels, and in formulations. Bacteria cannot thrive on anhydrous surfactants or in highly concentrated solutions and pastes; however, bacterial infection must already be expected in 20 to 30 % solutions of anionic or nonionic surfactants. Also, more highly concentrated solutions or pastes that tend to coacervate with the formation of low concentration phases can act as nutrient media for bacteria and exhibit signs of putrefaction. Bacterial infection must also be expected if highly concentrated surfactant formulations are handled incorrectly; small residues of surfactants in open vessels can be diluted by absorption of atmospheric moisture, and dilute surfactant solutions can accumulate on the floor or in dead spaces of vessels that have not been thoroughly cleaned with water. Cationic surfactants and amphoteric surfactants have a bactericidal action at and below the isoelectric point; except in highly diluted solutions (ppm range), a biodegradation of these surfactants can be ruled out.

Sterile conditions must be maintained to prevent premature biodegradation of surfactants during production. A sterile environment is generally ensured by maintaing high concentrations, high temperatures, and by using chemical bleaches. Transportation vessels can be filled in the hot state and thus under sterile conditions; the vessels must then be sealed in an air-tight and germ-proof manner. To protect surfactants against putrefaction during processing and in the dilute aqueous state (e.g., washing up liquids or shampoos), preservatives are added. Formaldehyde (0.1 – 0.3 %) is an excellent preservative, but has been discredited in some countries on account of its alleged carcinogenicity. Formaldehyde-releasing substances can also be used, for example, 2-Nitro-2-bromopropane-1,3-diol. 2-Methyl-3-isothiazolone, 5- chloro-2-methyl-3-isothiazolone, and 1,3-dicyano-1,2-dibromobutane are used in ppm amounts. 2-Phenoxyethanol, methyl and ethyl *p*-hydroxybenzoates and sorbic acid are effective at higher concentrations (ca. 0.5 %).

1. Introduction

Surgery in the late 1900s places heavy demands upon sophisticated technology, ranging from functional imaging equipment to assist in diagnosis, to lasers and robotics to improve accuracy and reliability. One of the most important areas in which technological advances have significantly enhanced surgery involves the use of synthetic materials for implantation in the body to assist in surgical reconstruction and repair. These surgical materials form an important subset of the more general group of materials referred to as "biomaterials", which are defined as materials intended to interface with biological systems to evaluate, treat, augment, or replace any tissue, organ, or function of the body [1].

Within the broad group of biomaterials, a number of subsets, including dental materials and drug delivery materials, may be distinguished (see → Dental Materials and → Pharmaceutical Dosage Forms). Surgical materials are defined in the context of this review as biomaterials used for implantation in the body to assist in surgical reconstruction and repair.

Biomaterials are rarely designed specifically for this use. Instead, they are generally materials developed for other applications but which have been found to be appropriate for medical use, often being modified or optimized for these applications. Thus the materials described in Chapter 4 are generally no different in structure and properties to materials used in chemical, aerospace, nuclear, and other industries. It

is the matching of the properties of materials to the specific and unique requirements of surgical reconstruction that is the key to biomaterials science.

2. Surgical Applications of Materials

In this section the reasons why materials are used surgically and the criteria for materials selection that can be established on the basis of the functional performance required are reviewed. General reviews of the clinical applications of materials may be found in [2–6].

2.1. General Principles

Biomaterials are implanted in the body for many different reasons but these can be broadly grouped as follows.

Congenital Deformities. Children are often born with a physical deformity which results in functional or aesthetic impairment. In some cases, the consequences may be life threatening, as with certain deformities associated with spina bifida, while in other cases they are more psychological, as in the case of facial disfigurement. The treatment and the precise usage of the materials vary from one situation to another.

Developmental Defects. A child apparently healthy and normal at birth may develop abnormally, perhaps due to impaired hormonal function, leading to defects that require correction. This usually involves the skeletal system, and procedures such as leg-lengthening and spinal curvature correction are included in this category.

Trauma. At any time in life, injuries may be sustained which require surgical intervention as part of the treatment. This may involve the use of materials and devices to assist the body to repair itself, such as sutures to close soft tissue wounds and fracture plates, nails, and screws to facilitate bone repair, or may involve structures that replace or augment damaged tissue, such as artificial skin, bone substitutes, ligament prostheses, and nerve guides.

Disease. The majority of diseases can be treated nonsurgically. However, a significant number affect tissues, leading to pain, loss of movement, or loss of vital function, such that surgery becomes essential. Specific examples involving the use of surgical materials in reconstruction include osteo- and rheumatoid arthritis, which may be treated by total joint replacement; atherosclerosis within the vascular system, which can be surgically treated with artificial arteries; and cataracts of the eye, which can be excised and replaced by intraocular lenses. Of great importance here is the order of preference in treatment: (1) nonsurgical methods (e.g., drugs); (2) minimally invasive procedures in which the defect is treated remotely or endoscopically; (3) surgical reconstruction involving the patient's own tissues, such as bone or skin grafts; and (4) reconstruction involving surgical materials. Thus, these latter procedures are only used when other treatments are ineffective or inappropriate.

Psychological Factors. There are many occasions in which adults find that their appearance causes them psychological problems. Under such circumstances, even when there is no medical or physical disability and where few others would agree that the appearance requires correcting, surgery, usually minor plastic surgery, may be carried out.

Tissue Atrophy. As part of the ageing process, tissues change their shape and consistency. In particular, some tissues lose their form and so augmentation or restoration is desirable. This may relate to loss of bone, especially in osteoporosis.

2.2. Orthopedic Surgery

Orthopedic surgery has historically been the most significant user of biomaterials. It is concerned with the musculoskeletal system and the treatment of diseases and disturbances to its components, particularly bones, cartilage, ligaments, muscles, and tendons. It is this system that produces movement and that responds to forces. It is therefore susceptible to injury and to stress-related diseases, the consequences of

which are significant since they affect the ability to move. Of equal importance is that any replacement of these tissues has to perform in the same mechanical environment, and attainment of the relevant mechanical performance is not a trivial matter.

2.2.1. Bone and Joint Replacement

Several diseases affect the bones and joints but they predominantly include osteo- and rheumatoid arthritis. These conditions affect the tissues of the joints, osteoarthritis being largely a mechanical disruption to the cartilage and underlying bone, while rheumatoid arthritis is an inflammatory disease which causes very painful structural changes to the tissues. Pain relieving drugs and anti-inflammatory agents may be reasonably effective but the diseases are progressive and in many cases, excision of the affected tissue is the only long-term solution.

Since in most cases the disease affects much of the joint, it is usual to resect a considerable amount of tissue and use a total joint replacement prosthesis. In the hip, for example, the first joint to be replaced in this way, it is usual to replace both the head of the femur and the socket within the pelvis (the acetabulum) [7]. In the knee, which is equally affected but more difficult to replace, the lower end of the femur, the upper end of the tibia, and the patella are involved [8].

The main requirements for these joint replacements are the ability to transmit forces under sliding conditions and the ability to be attached to the remaining bone, with durability measured in decades. Combinations of materials that give low friction and high wear resistance for the articulating surfaces are used, for example, a metal or ceramic bearing against ultrahigh molecular mass, high-density polyethylene, high-strength alloys for the main structural components [9], and a system to permit fixation to the bone. In the latter case, this is most often achieved by using a so-called bone cement, generally an in situ curing poly(methyl methacrylate) [10], or sometimes by means of a porous surface which allows ingrowth of bone to achieve stability [11], or bioactive coating that encourages rapid regeneration of bone at the interface [12].

Joint replacements are not without their problems but are generally able to provide pain-free movement for patients for a reasonable length of time. Whilst at one stage success rates, at least in hips, were high with an expectation of 15 – 20 years performance, as the age range in which these prostheses are used has widened, particularly as younger and more active patients have been treated, the demands on them have escalated resulting in reduced performance. An increasingly common problem is that the prostheses become loose. The principle causes of this loosening are the tissue reaction to the wear debris produced at the articulating interface [13], and the difficulty of attaining and retaining an acceptable stress distribution in the prosthesis – bone system [14]. It is for these reasons that attempts to enhance wear resistance and fixation with surface modifications and the introduction of composite materials to facilitate load transfer are being carried out (see Chap. 4).

2.2.2. Ligament Augmentation and Repair [15]

Ligaments are dense bundles of tissue, mostly composed of the structural protein collagen, that are attached to the bones within a joint and provide stability and constrain movement to acceptable limits. Damage to ligaments severely compromises this stability and therefore restricts the controlled movement of the patient. Ligaments rarely suffer disease, primarily because of their simple construction but they are very susceptible to injury, especially sports injuries. Here it is the ligaments of the knee, especially the cruciate ligaments which are frequently affected. Loss of function of these ligaments makes walking impossible.

Surgical treatment can take several forms. It is possible to attempt reconstruction by total replacement of the damaged ligament with a prosthesis; however, matching the elastic characteristics of the natural ligament and producing a reliable anchorage to the bone are difficult. The alternative is to use an augmentation device in which an implant is added to the damaged tissue and works with it to transmit the forces. Materials used in these types of device include polyester fibers, carbon fibers, and expanded polytetrafluoroethylene (PTFE).

2.2.3. Fracture Fixation

Bone possesses an extremely efficient mechanism for self-repair. Thus, when bone fractures, it heals spontaneously such that the newly formed bone is microstructurally indistinguishable from the existing bone. However, the repair only occurs with the appropriate alignment and geometrical arrangement if the fracture surfaces are held together in their correct position, without gross movement, during the healing process, which may take a few months.

With the long bones, such as the femur, tibia, and humerus, correct alignment and stability can be achieved by using a plaster cast. However, there are many occasions were this is not possible, perhaps because there are multiple fragments. In this case, surgical intervention is necessary to achieve the correct juxtaposition of the bones and to hold them in this position. This may be done through the use of various types of plate, nail, screws, or other fixtures. Although there have been a few attempts to use other materials, the vast majority of these devices are made from metals, which must combine the properties of strength, especially fatigue strength, with corrosion resistance and biocompatibility [16].

Because bone is a dynamic tissue that requires the stimulus of mechanical stress for maintenance of its internal structure, problems arise if rigid metal plates are retained within the bone after healing [17]. Ideally, all fracture plates should be removed once healing is complete; because of the slight risks involved with this additional surgical procedure, attention is now on the development of biodegradable fracture plates [18], which is difficult since the requirements for degradability and inherent strength are almost mutually exclusive.

2.3. Maxillofacial Surgery

Closely allied to the problems of the skeletal system are those concerning the structural tissues of the head, mostly involving bone but also the associated soft tissue. Here, however, the causes of the problems are a little different, as are the solutions. There are many subspecialities, including oral surgery, craniofacial surgery, orthognathic surgery, and perhaps more conveniently as an all-embracing term, maxillofacial surgery. The most important aspects follow [19].

2.3.1. Dental Implants

The area of dental implants lies at the interface between surgery and dentistry as far as biomaterials are concerned. The loss of natural teeth, through either disease or trauma, has, for many years, been compensated by the provision of artificial teeth in the form of bridges or dentures. These essentially provide an esthetic replacement of the crown of the tooth but do not replace the root and its attachment to the bones of the jaws. Whilst they are quite satisfactory in many patients, a number of disadvantages exist including the need to interfere with adjacent teeth when a bridge is used, and the problems of denture stability, and so it has long been the ambition of dentists to use implants that replace teeth in their entirety. This is difficult because the implants contact a number of different types of tissue, including an epithelial barrier, must reside in the microbiologically hostile region of the mouth, and are exposed to a complex stress system without much support. For many years, a very poor success rate reflected this difficulty, but more recently, improvements to materials, designs, and techniques have given far better performance and dental implants now represent a very respectable alternative to traditional dentures [20–22]. The materials of choice are titanium alloys (see → Dental Materials, Chap. 2.3.2.) and alumina, often coated with a porous surface or bioactive material such as calcium phosphate (see → Dental Materials, Chap. 2.5.).

2.3.2. Maxillofacial Trauma

Fractures of the facial skeleton have traditionally been treated conservatively; in contrast to fractures of the long bones, which are often compound and displaced, those of the face are usually simple without distortion of shape. The requirements for stability are more easily satisfied, for example, by interdental wiring or external halos which consist of a frame secured to the skull by means of pins. However, it is becoming increasingly recognized that better results and far more convenience to the patient

can be achieved through the use of internal plating. Small titanium or stainless steel plates for the fixation of mandibular or maxillary fractures are now widely used [23]. The requirements for degradability mentioned in Section 2.2.3 also apply here, and the less severe mechanical environment makes this a more realistic possibility.

2.3.3. Reconstructive Maxillofacial and Orthognathic Surgery

The connective tissues of the head and neck also suffer from a variety of diseases and deformities that may require treatment. These range from inflammatory disease of the periodontium, the tissues that support the teeth, to extensive hard and soft tissue tumors. The treatment of advanced periodontitis may involve the implantation of thin strips of a porous material around the root of the tooth, such as expanded PTFE, which facilitate the regeneration of new connective tissue and act as a barrier to infection, or the implantation of artificial bone. The latter approach may also be used in patients who suffer localized osteoporosis, with substantial loss of bone, within mandible or maxilla after tooth extraction.

Tumors of the head and neck present considerable problems of reconstruction [24]. This is partly because prior irradiation treatment used in an attempt to eradicate the tumor severely compromises the ability of the tissue to heal and to accept the presence of an implanted device. If the tumor affects the bone, it is necessary to remove a large amount of that bone, which makes reconstruction by a prosthesis, with attachment to the remaining part of the facial skeleton, very difficult. This is a particularly challenging area of implant surgery.

2.4. Cardiovascular Surgery

Diseases of the circulatory system occur as frequently as those of the musculoskeletal system but, by their very nature, are more life threatening than immobilizing. The diseases can affect the heart, the major circulatory system, and the microvasculature, the consequence of which is a perturbation to the flow of blood. Treatment that does not require major intervention is preferred, for example, pharmacological and endoscopic techniques.

2.4.1. Heart Valves

The valves of the heart control the flow of blood into and out of the chambers. There are four valves of interest: the mitral, aortic, pulmonary, and tricuspid, and their opening and closing mechanisms slightly differ, as do their susceptibility to disease. The mitral and aortic valves are the most critical in this respect, suffering from two major modes of malfunction, stenosis and incompetence. *Stenosis* is an obstruction of the valve orifice which disturbs the pattern of blood flow and increases the pressure necessary to achieve adequate flow. At these high pressures, turbulence becomes more significant and considerable stress is placed on the heart. *Incompetence* arises from the inability of the valve to close properly, allowing a retrograde flow back through the valve, again disturbing the flow profile.

When valvular disease has progressed to such an extent that it compromises the ability of the heart to maintain the circulation, it becomes necessary to remove the offending structure and replace it with a prosthesis [25]. This has been possible for over thirty years. The original valves consisted of a ball held within a cage which was sewn into the heart. These worked reasonably well although not without problems and the valve, both with respect to materials and design, has evolved over the years [26]. The common designs incorporate a flat disc that tilts within a mechanical constraints, or flaps which open and close on a pivot or hinge. Although mechanical failures may occur with such devices, which are usually catastrophic and fatal [27], the main problem arises from the thrombogenicity of the materials used. This means that there is a tendency for the blood to clot on the surface of the valve and, as a consequence, all patients fitted with them have to regularly take anticoagulant drugs.

Because of this, there have been attempts to produce valves that are more compatible with blood and which are able to open and close in a more physiological mode [28]. The development of the so-called bioprosthetic valve that is made of natural tissue, derived usually from the muscle wall of cows hearts or the valves of pigs

has ensured. These valves do not require anticoagulants but are susceptible to slow deterioration and calcification, necessitating periodic replacement [29].

2.4.2. Vascular Prostheses

Atherosclerosis is a condition in which deposits building up along the inner surface of blood vessels, especially the arteries [30]. The resulting stenosis interrupts blood supply and places the heart under considerable strain. Most arteries can be affected. When the coronary arteries are involved, the blood supply to the heart itself is interrupted, leading to a heart attack. If an artery in the lower leg is affected, for example, the femoropopliteal artery, the result is restricted circulation to the feet and, eventually, gangrene. The deposit that forms involves a collection of cells and proteins which can sometimes be broken up using drugs. More usually, by the time the condition is diagnosed, it is not treatable in this way. It may, however, be amenable to endoscopic techniques, which involve the insertion of a device into the vessel, its guidance to the site of the blockage, and the removal of the deposit, either mechanically, or by laser ablation [31]. If these angioplasty techniques fail, or if the problem recurs, then reconstruction may be the only option. Ideally the vascular surgeon will choose to use a vein or artery graft, i.e., transposing a vessel such as the saphenous vein or internal mammary artery to the critical, damaged site [32]. This works well under most circumstances, but it is not always possible to obtain a suitable source and very difficult to find large segments. Under these circumstances, artificial arteries, often incorrectly termed vascular grafts, may be employed [33]. Their design is crucial, as is the material and method of construction chosen for the tubular structure. Without exception, successful artificial arteries employ microporous polymers, either woven or nonwoven, such as expanded PTFE [34] or polyester textiles [35]. Their mechanical characteristics, such as compliance and kink resistance, and their compatibility with blood components are critical.

2.4.3. Extracorporeal Circuits

Although external life support systems are not included here within the definition of surgical materials, it is important to recognize that extracorporeal circulation is extremely common. The best examples are the hemodialysis machines, oxygenators, and liver perfusion equipment. In all these cases, blood is removed from the patient and treated by circulation through tubing, over membranes, or through columns (for example, to remove toxic metabolic products). All the concerns about blood flow and compatibility between blood and materials discussed in relation to implantable devices are also relevant here [36].

2.4.4. Cardiac Pacemakers

Conditions other than the mechanics of blood flow may affect the ability of the heart to function correctly, particularly if there is discontinuity in the conduction of stimuli from the nervous system. If there is such a disturbance, either permanant or transient, then an implantable cardiac pacemaker may be used to supply and deliver signals to the heart muscle to control the heartbeat. Pacemakers consist of a package of microelectronics, usually hermetically sealed inside a welded titanium casing, connected to the wall of the heart by an insulated lead, terminating in an electrode [37].

2.5. Ophthalmology

The structure of the eye is conceptually very simple, consisting of a collection of tissues and fluids that direct and focus incident light onto the retina, where the light energy is converted into electrical signals that are passed to the brain via the optic nerve. Blindness or partial loss of sight can arise from disruption to the light pathway, an inability of the retina to capture the light with appropriate fidelity, or a failure within the nervous system. Problems of the latter nature can rarely be remedied. However, there are procedures that can be used to reconstitute a light pathway that has been disturbed through disease.

2.5.1. Corneal Replacement

A common condition affecting the cornea is glaucoma, where there are inflammatory and structural changes in the tissues which prevent light passing through undisturbed. Glaucoma can be treated by drugs but also by using grafts. Corneal grafting, using corneas derived from cadavers is one of the easiest types of tissue grafting. The cornea, an avascular structure, is far more easily tolerated by the body's immune system. On the rare occasion where corneal grafts are not possible, artificial corneas, the so-called keratoplasty prostheses, typically made of a clear plastic such as poly(methyl methacrylate) (PMMA), are available [38].

2.5.2. Intraocular Lenses

Cataracts, areas of the lens which become cloudy, are extremely common. Treatment involves excision of the lens, which leaves the patient with a severe visual defect. This can be compensated by spectacles, but not efficiently, and the treatment of choice is the intraocular lens [39]. This is a poly(methyl methacrylate) lens, usually discoid in shape, which has attachments around the periphery, made from either the same material or an alternative polymer and known as haptics. The plastic lens is placed within the eye at approximately the same location as the extracted lens. Although at one stage it was difficult to achieve a high level of success with these lenses because of the damage caused to the surrounding tissue and the resulting inflammation, improvements to the surface quality and to the implantation technique have resulted in considerable success for this quite simple structure [40].

2.5.3. Contact Lenses

Although not strictly implantable materials, contact lenses are usually worn as an alternative to spectacles for correction of vision but may also be worn for medical reasons. Contact lenses must have good optical properties and excellent compatibility with the cornea [41]. The cornea is an avascular tissue which derives its oxygen by diffusion through its external surface. This should be compromised by the placement of a plastic structure over the surface. For this reason it is better that the contact lens has high oxygen permeability. It should also produce minimal mechanical irritation to the sensitive corneal surface. Several materials are used for these lenses; hard lenses are usually made of PMMA, while soft lenses may be made of silicone elastomer or a hydrogel such as poly(hydroxyethyl methacrylate) [42].

2.5.4. Vitreoretinal Surgery

A far less common cause of visual defect involves damage to the retina or associated tissues at the back of the eye, mainly detached retinas. A variety of materials, mainly silicones, may be used in attempts to physically relocate and reattach the retina [43].

2.6. The Nervous System

Intuitively, the brain and nerves appear to be tissues far too sensitive to accommodate invasion by surgical materials. However, there are a variety of circumstances in which foreign materials have been placed within the central nervous system without apparent effect. The difficulty is actually achieving anything profitable as far as performance of the system is concerned. One simple but very important application within the brain is the insertion of a catheter into the lateral ventricles to allow the drainage of cerebrospinal fluid in infants with hydrocephalus, a potentially fatal condition associated with spina bifida [44]. The tolerance of brain tissue to biomaterials is also seen from the use of a variety of substances, including in situ curing acrylics, to seal cranial defects.

2.6.1. Nerve Repair and Regeneration

Nerve tissue does have the capacity for repair, but it is limited in extent and efficiency. Repair of peripheral nerve damage can be assisted by nerve guides, small tubular structures placed around the severed ends of a nerve, which allow the nerve tissue to regenerate and reconstitute the nerve pathway. Ideally the materials used should

actively encourage this growth, although simple polymers probably achieve their goal passively [45].

2.6.2. Nerve Stimulators in Pain Relief

Chronic, severe pain is extremely difficult to treat. It is known that electrical impulses can be applied to nerves to block the impulses transmitted to the brain, that give rise to pain. The use of implantable pain relief stimulators is relatively new [46]. The same principles of construction described for pacemakers apply.

2.6.3. Treatment of Hearing Loss

Sound is conducted to the brain via the ear. The middle ear, involving the three small ossicular bones (stapes, incus, and malleus), conducts sound waves to the tympanic membrane. The disease of otosclerosis causes inflammation and eventual fusion of these bones such that their ability to vibrate is compromised. These bones may be excised and replaced by quite simple structures which can themselves vibrate within the ear to conduct sound [47]. If the inner ear is affected by disease, treatment is far more difficult; indeed restoration of hearing to the profoundly deaf is virtually impossible in the vast majority of cases. Nevertheless, some progress has been made in the conversion of sound waves into electrical signals and delivering these directly to the cochlea [48].

2.7. General Surgery

2.7.1. Wound Closure and Artificial Skin

Although there is a very strong trend toward minimally invasive surgery, in which incisions are very small, there is still a considerable need for materials and techniques for wound closure. Traditionally, tissues have been closed with sutures. These are monofilament or multifilament threads, used to sew tissues together. They may be permanent, as with polypropylene sutures, or intentionally degradable and resorbable, either natural (catgut) or synthetic (some polyesters). Materials such as silk are used where long-term retention is required but where degradation eventually takes place [49].

Clips, usually metallic, are often used instead of sutures, largely because of greater convenience. In addition, there is much interest in adhesives. The specifications for surgical adhesives are, however, very strict especially in relation to the wet environment and the need to avoid toxic effects associated with a setting adhesive. There is still much progress to be made [50].

Artificial skin is required in situations where there is considerable skin loss, usually resulting from burns. Skin grafting is preferred, but where there is substantial loss of tissue and insufficient donor tissue, a synthetic alternative is desirable. Due to the complexity of skin structure and function this is a difficult task but some progress has been made with the use of a degradable polymer scaffold, infiltrated with epithelial cells from the patient prior to application [51]. This type of structure allows skin to regenerate within the matrix, which then degrades.

2.7.2. Soft Tissue Reconstruction

Many surgical procedures used for correction or reconstruction are simple and only involve the placing of a piece of soft plastic material into the body to alter shape or contour. Since these operations are largely cosmetic, they tend to concern the face and female breast. In theory they should be the simplest of procedures and provide the best results. This is not always the case, however, and significant problems have arisen over the use of some of these materials, especially the silicones and polyurethane-coated silicones used for breast prostheses [52]. These problems have considerably reduced public demand for such prostheses.

2.7.3. Surgery of the Urinary Tract

The urinary tract, including bladder, urethra, ureter, and associated tissues, suffers a number of diseases, primarily involving incontinence and infection, and a very large number of patients are affected. However, treatment of many of these conditions remains problematic and the use of materials to assist in reconstruction or restoration of function is not well established. It

is extremely difficult to use biomaterials within the urinary system, because of the need to regulate urodynamics, to avoid infection, and to resist encrustation. There is a considerable need for prosthetic replacements for these tissues and also for devices to effectively control incontinence [53].

2.8. Artificial Organs

Clearly some organs can be transplanted, and although there remain very many logistic and ethical issues, this must be considered the preferable mode of replacement. In many circumstances, however, this is not possible and an artificial device has to be considered. A number of years ago, an implantable artificial heart was used in a few patients but this was not particularly successful. It is unlikely that any of the major organs can be replaced by a synthetic substitute, simply because of their complex and multiple functions. Progress is being made in a limited number of situations in which synthetic materials can be used in conjunction with cells or tissues, derived either from the patient or a donor, producing a hybrid artificial organ. This is undoubtedly an area of high promise for the future.

3. Criteria for Materials Selection

[54]

A wide variety of functions are required from surgical materials and no single material or group of materials can satisfy all the conditions. It is necessary, therefore, to consider, generically, the requirements of biomaterials and to identify the key elements of materials selection. These can be divided into properties that determine suitability of the device to function, those which determine practical aspects of manufacture and supply, and, most importantly, the features of biocompatibility.

3.1. Mechanical and Physical Properties

Although surgical materials are intended to replace, both in structure and function, the diseased or otherwise damaged tissues, the performance required of surgical materials is generally quite limited and largely restricted to space filling or mechanical performance, either structural or fluidic. There are some circumstances where physical properties are critical, and some situations where biological performance is required are emerging.

3.1.1. Mechanical Performance

Since the tissues to be replaced vary from the extremely hard enamel to the very soft lens, and from the rigid cortical bone to the very extensible arterial wall, a generalized mechanical performance for surgical materials cannot be specified. However, there are a number of important general points.

Strength is always important and it is crucial that stress systems within the material – tissue complex are established and performance specifications, with respect to both yield and fracture strength, determined. Finite element analyses are increasingly being used for this purpose, and the stresses generated within the human body are often surprisingly high. Because the body is a dynamic medium, both viscoelastic and fatigue behavior are crucial. Nevertheless, these mechanical considerations per se should not be serious limiting factors, since, with a few exceptions, there are sufficient materials available, off-the-shelf, to satisfy these needs.

With respect to *elasticity*, the most important aspect is the matching of the elastic constants and deformation behavior of devices to the requirements of the body. Ideally the rigidity, flexibility, compliance, or other characteristics of elastic deformation should enable the device to participate in the transfer of load and movement exactly as if it were the natural component. Failure to do so can have major consequences, both in relation to device function and to the overall effect on the body.

Because *mechanical performance* must be achieved within the chemically hostile environment of the tissue fluids, mechanical – environmental failure modes, such as stress corrosion cracking, corrosion fatigue, stress crazing, stress accelerated macromolecular degradation, and hydrolysis induced delamination of composites, may occur.

3.1.2. Electrical and Optical Properties

Electrical and optical properties are the two most significant physical properties. In some situations electrical conductivity is required, as in pacemaker or stimulator electrodes while in other cases, as in their coverings, insulation is necessary. Electrodes delivering signals to tissues are often made of noble metals, particularly platinum group alloys, because of the need for inertness under conditions in which charge has to be transferred across the interface, without the simultaneous transfer of toxic metal ions. Because of inherent difficulties here, there is much interest in other conducting materials such as conducting polymers. Insulation is not normally too much of a problem although the diffusion of body fluids, themselves electrolytes, into polymers has to be taken into account when considering long-term performance.

Optical properties are reasonably straightforward, there being a small range of optically clear amorphous polymers available. Poly(methyl methacrylate) is usually preferred.

3.2. Manufacturing and Sterilization

3.2.1. Constraints on Fabrication

The very significant advances in manufacturing technology and process engineering imply that there should not be too many problems over the fabrication of medical devices. The one major factor to consider is that no two patients are alike and that ideally many of the devices should be custom-made. This becomes difficult technically since usually prior to an operation the extent of tissue resection is not known and, therefore, the shape of the prosthesis cannot be predetermined. Nowadays, a variety of shapes and sizes have to be made available and hospitals are required to hold a large inventory so that the nearest fit can be used. In the future there will be more emphasis on the use of medical imaging techniques to determine the extent of the disease and predict the shape that will be required, and of CAD/CAM techniques for customized fabrication [55].

3.2.2. Market Analyses [56]

One of the main constraints to the supply of both materials and devices is the size and fragmented nature of the market. Whilst it is often thought that the medical device area, like the pharmaceutical industry, commands very high prices, and that markets are very large, in reality it is not quite so simple and many clinical conditions are not sufficiently common for manufacturers to take the risks associated with small production runs. Of even greater significance is the fact that raw materials suppliers usually do not benefit from the high unit prices of medical devices, but carry responsibility for quality. Few are, therefore, willing to supply small amounts of medical-grade materials to this industry.

3.2.3. Legal and Regulatory Constraints

There are quite severe regulatory constraints on the use of surgical materials in medical devices. In the United States, the industry is regulated by the Food and Drug Administration (FDA) while the European industry is now coming under the control of the European Community (EC) Medical Devices Legislation. There are stringent requirements concerning biological testing and conformity to certain requirements, especially quality control.

3.2.4. Sterilization Techniques [57]

The implantation of a medical device into the body carries with it an inherent risk of infection. Of course any operative procedure is associated with a finite risk but the use of materials placed within tissue considerably enhances that risk. It is extremely important, therefore, that the risks are minimized by appropriate sterilization of the devices. Care has to be taken since all of the available techniques can adversely affect some of the surgical materials. For example, two processes rely on heat to kill bacteria, either by dry heat or with superheated steam (autoclaving), the temperatures involved affecting many plastics. The main alternative is gamma irradiation, whereby the free radicals generated during this process can have significant and deleterious effects on many materials. The third method

involves chemical agents, principally ethylene oxide. Whilst effective, it is very difficult to remove all residues from the materials, potentially leading to toxic or irritant effects, and it is likely that this process will be prohibited in the future.

3.3. Biocompatibility [58]

The interactions between surgical materials and their host are the most influential factors determining their performance, especially in the long term. Biocompatibility can be defined as the "ability of a material to perform with an appropriate host response in a specific application" [1]. It must be emphasized that the range of materials in use today has been based on the assumption that biomaterials have to be inert and have no effect on the tissues. Whilst this may be appropriate under many circumstances, and while we never wish there to be adverse effects, it is now considered that the total lack of interaction implicit in that concept is not appropriate to the use of devices that are intended to become incorporated into the body, both anatomically and functionally, and that a distinctive and positive interaction is a far better goal. It is this concept that underpins the following discussion and which explains the developments in materials and especially their surfaces.

3.3.1. General Principles

Biocompatibility is concerned with all of the reactions and effects that take place between a material and the body [59]. It is possible to distinguish several groups or types of reaction in order to identify mechanisms, although all are potentially mutually interdependent. These categories of reaction are determined by the location of the effect.

Firstly, upon immediate exposure of the material to the tissue fluids, whether that be blood, serum, saliva, tears, or extracellular fluid, molecules are adsorbed from the fluid onto the surface. These are usually proteins, of which there are many different types in all body fluids and the characteristics of the adsorbed layer may significantly influence subsequent events. Of particular importance are the selectivity of the process, the changes to the conformational state of the proteins after adsorption, and the dynamics of adsorption and desorption as a multilayer is established. At this point, it is still difficult to identify which material characteristics control these phenomena.

Secondly, there are the effects of the tissues on the material, particularly in relation to corrosion and degradation mechanisms.

Thirdly, and usually of greatest significance, there are the effects of the material on the tissues adjacent to the device; these effects vary from one site to another and with time.

Fourthly, there is the possibility that the interfacial reactions and the systemic transport of reaction products away from the interface can give rise to remote effects, perhaps at the site of deposition or accumulation of these products.

3.3.2. Corrosion and Degradation

The environment of the human body is surprisingly hostile to synthetic materials. It is an isotonic saline solution with a variety of additional anions and cations and a range of biological macromolecules, free radicals, and cells, all of which have the potential to be biologically as well as chemically active. For metallic materials, the saline electrolyte ensures a highly corrosive environment [60], although it is known that the proteins present can also influence corrosion processes, especially if the metal concerned is able to bind to proteins [61].

Because of this aggressiveness, only the noble metals and those that are passive under physiological conditions can be used (see Section 4.1).

With ceramics, the behavior varies considerably [62]. Whereas oxide ceramics such as alumina and zirconia are extremely stable, some calcium-based ceramics are used which are degradable over a relatively short period. It is not quite clear whether this is a passive dissolution process or whether specific biological activity is implicated. It is instructive to note, however, that natural coral is used as a biomaterial; in the oceans, coral is stable over thousands of years but within the body, it may dissolve in months. Coral mainly consists of calcium carbonate.

Polymeric materials are the most difficult to judge from the degradability point of view. Polymers are normally degraded by physical

agencies such as heat, light, and ionizing radiation (which are absent in the body) so that they should be largely protected. However, some are susceptible to degradation by hydrolysis, and active molecular species within tissues, particularly free radicals and enzymes, can participate in degradation mechanisms [63], [64]. There is, therefore, a spectrum of behavior ranging from some homochain, nonhydrolysable, hydrophobic materials such as polytetrafluoroethylene, which appear to be nondegradable, to hydrolysable and rapidly degradable polymers, always heterochain and usually with carboxyl groups such as the aliphatic polyesters [65]. In the middle are a selection of polyamides, polyurethanes, polyesters, and many others which slowly degrade, perhaps over years, within the body. This degradation can affect device performance, for example, the eventual rupture of a polyester artificial artery [66], or affect the tissue response [67].

3.3.3. Soft Tissue Biocompatibility

It is still uncertain exactly what device characteristics determine the host response, but some general principles can be described. It is convenient to regard these on a temporal basis and to consider the response as a perturbation to wound healing, repair, and remodeling processes that occur in response to tissue damage [68]. If the surgical implantation of the material into an area of soft tissue is thought of as an injury, the effects of the material itself can be analysed as a superimposition onto the effects of the surgery. Inflammation results whenever tissue is damaged and has to be recognized as an inherently desirable response under these circumstances since it is designed to eliminate the source of the irritation (e.g., bacteria). Inflammation involves changes to the microvascular network and the infiltration of large numbers of cells into the area. If the source of the injury can be eliminated and any debris removed, both being brought about by the activity of these inflammatory cells, then a repair process is initiated, and the inflammatory cells slowly withdraw. In soft tissue, the repair process is normally controlled by fibroblast cells which synthesize collagen, a protein that constitutes scar tissue.

A biomaterial placed at the site of a surgical incision may interfere with either or both inflammatory or repair processes. With a totally chemically inert material, however, these opportunities are minimal and it is likely that inflammation and repair will proceed as normal, the only influence of the material being as a physical barrier to regeneration. Classically, the implantation of a sample of an inert biomaterial into soft tissue results in the formation of a thin layer of fibrous tissue, structurally analogous to scar tissue, that surrounds or encapsulates the implant [69].

If, however, the implant is not inert, which is usually the case, the reactions that take place will influence events. They may aggravate and extend the initial acute inflammatory response. More importantly, the continuation of interfacial reactions means that there remains a persistent stimulus to inflammation resulting in a chronic inflammatory response, merging with a delayed and continuous fibroblastic reaction. Their effects on the performance of the device and the health of the patient vary considerably, but if uncontrolled they are likely to lead to cell and tissue death. Moreover, these interfacial reactions usually initially involve the release of some component from the material into the tissue, either a corrosion or degradation product, or a leachable residue. The development of the inflammatory response, in which large numbers of cells are attracted to the area and activated to release large quantities of superoxide ions and oxidative enzymes, for example, rapidly increases the aggressiveness of the tissue, causing further and enhanced degradation of the material. The process is, therefore, autocatalytic [70].

The precise features of the host response are highly dependent on the individual circumstances. Material characteristics obviously influence events, particularly with respect to bulk and surface chemistry, rates of degradation, and the nature of the degradation products and physical features such as surface finish, size, and shape. Of equal importance are the patient variables, such as location of the device and age, sex, activity, general health, and pharmacological status.

3.3.4. Hard Tissue Biocompatibility

Concerning location, one type of tissue, bone, is extremely important, for the host response is a little different and the consequences of enor-

mous importance. The critical aspect is the ability to attain and maintain good apposition and preferably adhesion to bone, especially with joint replacements [71]. If the prosthesis is loose or becomes loose, then it will fail. If the generalized reaction of tissues to materials is, after inflammation and repair, a zone of soft collagenous tissue around the device, and if this were to take place around a material placed within bone, then it would be impossible to obtain the necessary attachment. It is essential for there to be a bone – material interface without an intervening layer of soft tissue. This inherent mechanism of fibrous encapsulation, therefore, has to be avoided or suppressed. This has been largely attempted through the use of materials of maximal inertness, such as titanium, alumina, poly(methyl methacrylate), or polyethylene. Of considerable current interest is the approach involving materials that are positively attractive to bone, the so-called bioactive materials, such as calcium hydroxyapatite [72], which permit preferential formation of bone rather than soft tissue at the interface.

The acquisition of a direct interface with bone is important, but so is its retention. Two factors may contrive to destroy such an interface. Firstly, as bone is a dynamic tissue it is dependent on the appropriate level of mechanical stress for it to maintain its normal structure and architecture. Without stress, bone will resorb. With the wrong type of stress, which results in relative movement between bone and prosthesis, resorption will occur. It is vital to ensure the optimal stress distribution in the bone – prosthesis system in order to maintain the bone; failure to do so, arising from poor materials selection, design, or technique, will result in the prosthesis becoming loose [73]. Secondly, if restimulation of the inflammatory response occurs, this could cause resorption through cellular activity. The main causes here are wear particles generated at the bearing interface in total joints [74]. Depending on their rate of release and the particle size, a significant chronic inflammation can arise, some of the cells involved also having the capability of destroying bone. This is probably the ultimate limitation to the performance of orthopedic prostheses.

3.3.5. Blood Compatibility

Just as the interactions between materials and bone control the performance of orthopedic prostheses, so the interactions between materials and blood control the performance of all intravascular and extracorporeal circulatory devices. These are extremely complex since they involve so many different components and mechanisms (see Section 2.4). The principle points are as follows [75].

The initial event when blood flows over a surface is that some plasma proteins are adsorbed onto that surface. The nature of the resulting *protein layer* varies from one material to another and with time. A thin layer of protein on a surface is not inherently undesirable in most circumstances; with the exception of intravascular sensors where the layer may disturb analyte transport. However, it is this protein layer which determines whether blood will clot on the surface, primarily through its effect on clotting cascade proteins and platelets [76]. The former process involves a sequence of enzyme-catalyzed reactions in which various circulating proteins are sequentially transformed into fragments, resulting in conversion of prothrombin into thrombin, which catalyzes the conversion of fibrinogen to fibrin and its subsequent polymerization. For reasons which are not entirely clear, some surfaces are far more likely to activate this sequence of events than others [77].

The second process is *platelet activation* [78]. These cells do not normally interact with the surface of blood vessels; they only do so when the vessel is damaged and then the interaction is very valuable in hemostasis. Unfortunately, the conditions which arise when a foreign surface is exposed to blood are similar to those of a damaged vessel surface, and the platelets react in the same way. A few platelets are attracted to the surface and activated. A series of chemicals are released from these activated platelets attracting vast numbers of other platelets which form an aggregate. The combination of polymerized fibrin and platelets constitutes a blood clot or thrombus, which is both damaging to device performance and compromises the health of the patient.

The selection of blood-contacting biomaterials is determined by the need to minimize this tendency. There are several possible approaches.

First, extreme inertness may yield relatively nonthrombogenic surfaces, such as PTFE, although this is no guarantee. The second approach is to use materials which inhibit or prevent these processes from taking place. This usually involves treating a surface with a substance which interferes with the clotting process (e.g., heparin [79]), or with the platelet adhesion process (e.g., prostacyclin [80]). Thirdly, the surfaces can be prepared such that they mimic the natural surface, as with the attachment of phospholipids to polymer surfaces [81], or are partially made of natural components such as surfaces seeded with endothelial cells [82].

Currenty, there is no universally blood-compatible material or surface but these approaches provide a promising future.

3.3.6. Systemic Biocompatibility [83]

If the products of an interfacial reaction can be transported away from the site, either by passive diffusion through the tissues or actively within lymphatic or vascular systems, there is the possibility that they could promote effects at some point distant from the site of application of the device. There is little evidence of this, but by the very nature of the phenomenon, evidence would be hard to obtain. The greatest fear here is that the products could accumulate in a sensitive area and cause serious effects where there was no obvious causal link to the device; the risk of biomaterial-induced cancer is at the forefront of these concerns [84].

3.3.7. Bioactivity

Inertness and lack of biological recognition is not always desirable, and a more active role for the material may be preferable. There are at least two possible mechanisms by which these so-called bioactive materials could operate, either through the inhibition of undesirable events or through the promotion of desirable events. Examples have already been given for bioactivity in the cases where bone adaptation has to be encouraged and where blood interactions have to be controlled. Further examples can be found in Chapter 4.

4. Materials

An encyclopedic review of biomaterials is given in [85]

4.1. Metals and Alloys

Metals are primarily employed in situations requiring their unique combination of mechanical properties, particularly fatigue strength, toughness, and ductility. Also when electrical conductivity is needed, metals are the materials of choice.

Because the mechanical specifications can be met by many alloy systems, considerations of biocompatibility, and especially corrosion resistance and toxicity, are decisive. It is possible to use the corrosion resistance of noble metals, and indeed, platinum group metals are used in electrical applications, gold alloys in dentistry, and silver in a variety of circumstances due to its antibacterial activity. However, these noble metals do not generally have sufficient strength, and so engineering alloys are preferred. These have to be of exceptional corrosion resistance and it is only passive alloys that can be considered. These are based on the passivity of chromium or titanium.

Steels. Stainless steels rely on chromium for their passivity and provide good corrosion resistance under many conditions. However, the physiological environment is such that their corrosion resistance is marginal, and only a small group of austenitic stainless steels are used, particularly AISI 316L [86–88]. These alloys possess a good combination of properties, but their popularity is declining in view of the enhanced performance of the alternatives discussed below.

Cobalt-Based Alloys. For over sixty years, alloys of the Stellite variety have been used in dentistry and surgery. These are alloys primarily of cobalt and chromium, in solid solution, with a variety of other elements to confer specific properties. Initially these alloys, with additions of molybdenum, nickel, and carbon gave a good balance of properties but the very restricted ductility limited the alloys to situations in which

they could be cast. Variations in alloying additions then permitted conventional forging operations to be used and now a wide variety of formulations and production technologies provide some extremely good properties [89]. The corrosion resistance is better than that of stainless steels and the excellent hardness makes these alloys the materials of choice for one of the bearing surfaces of many joint replacements. The main drawback lies with the putative toxicity of cobalt and chromium, although the significance is questionable.

Titanium and its Alloys. Titanium is the most corrosion-resistant non-noble metal in physiological fluids and is widely used in medical applications. It does not have sufficiently good mechanical properties for it to be used as the pure metal in most circumstances and so, for structural applications, alloys are employed. For many years, the $\alpha + \beta$ alloy Ti – 6 % Al – 4 % V has dominated the scene, but more recently, a few others have been introduced. The rationale for this has been a concern over adverse effects of aluminum and vanadium, but again these are speculations rather than objective decisions and there is no evidence of such adverse effects. Indeed, for many applications, the Ti – Al – V alloy possesses the best combination of mechanical, corrosion, and biological properties [90], [91]. Two points about the orthopedic uses of titanium should be noted. First, it has an elastic modulus, ca. one half that of either steel or cobalt alloys and is, therefore, more closely matched to bone with respect to rigidity. Secondly, its wear resistance is considerably inferior to these alternatives and its use as the bearing surface in joints is not recommended.

Platinum Group Metals. The inertness of platinum coupled with its excellent electrical properties suggests that it should be very appropriate for electrodes. Because implanted electrodes are subjected to forces within the body, mechanical performance is important, and certain alloys, such as Pt – Ir or Pt – Rh, may be superior [92].

Other Metals. There are few opportunities for other metals in the body. As noted above, silver is of interest because of its antibacterial activity [93]. One other possibility is the use of shape-memory alloys for intravascular strents, orthodontic wires, and orthopedic devices, where Nitinol, a nickel – titanium alloy is the most obvious candidate [94].

4.2. Ceramics and Glasses

Until a decade ago, the inherent brittleness of ceramics precluded their use in critical structural applications within the body. However, advances in ceramic processing technology have enabled significant improvements to fracture strengths and toughness to be obtained and now ceramics, and their amorphous counterparts the glasses and glass ceramics, are frequently used in these applications. There are three qualities of ceramics with underpin these uses, the inertness of certain oxide ceramics, their hardness, and within a small group, a degree of bioactivity.

Oxide Ceramics. Some of the simplest ceramics, those combining one metal with one nonmetal, provide the best properties. In particular, when the nonmetal is oxygen, a small series of extremely inert and hard ceramics may be distinguished. Of these, alumina (aluminum oxide), is the most widely used in surgery [95], [96]. Although there have been a few reports of property changes to alumina on implantation, this is not a significant problem, and the long-term biocompatibility is exceptionally good. The hardness is responsible for the selection of alumina as the bearing surface in many hip replacements. While the strength is reasonably high, its toughness is still only marginally acceptable, and there have been problems of brittle fracture in joints where alumina has been used for both femoral and acetabular components. There has, therefore, been a move toward tougher ceramics, particularly transformation-toughened, partially stabilized zirconia [97].

Calcium-Based Ceramics. Calcium compounds are not renowned for their mechanical properties nor for their hardness, but the chemical and structural similarity between some calcium compounds and the mineral phase of bones and teeth is attractive for certain medical purposes. This phase is essentially calcium hydroxyapatite, a hydrated calcium phosphate.

Calcium Phosphates. Synthetic calcium phosphates can be placed in contact with bone and stimulate bone regeneration [98]. These cannot be used in a structural capacity, but there are several forms which are of interest. Of the *chemical variations*, the two main forms are calcium hydroxyapatite and tricalcium phosphate. The former is essentially stable, while the latter is rapidly degradable. There are also *structural variations*. The materials can be used in particulate form, whereby a quantity may be placed within defects in bone, in a similar way to that employed for bone grafts. New bone forms around the particles, which effectively act as a scaffold. With the nondegradable calcium hydroxyapatite, the result is a composite structure of biomaterial and new bone; with the degradable tricalcium phosphate, new bone may continue to form as the particles degrade, resulting in total bone restoration. Bone defects in the facial skeleton and the spine may be treated in this way [99], [100].

Calcium Carbonates. Some forms of calcium carbonate are also able to demonstrate bioactivity with respect to bone. In particular, coral, a natural form of calcium carbonate, is very effective in stimulating bone ingrowth and regeneration; the coral degrades over months and is wholly replaced by bone [101].

An alternative use is as a coating on a tougher substrate. In particular, hydroxyapatite is frequently applied by plasma spraying to metallic prostheses to encourage adaptation of bone [102].

Glass Ceramics. While the oxide ceramics are completely stable and materials such as coral are totally degradable, some ceramics and glass ceramics display intermediate behavior with a degree of surface degradation. These are often referred to as bioglasses. These are complex structures, based on oxides of calcium, silicon, sodium, and phosphorus. Interaction with body fluids causes dissolution of calcium and phosphorus, which appears to permit formation of new bone at the surface, but the reaction is limited by the establishment of a silica-rich layer. These controlled surface-reaction glass ceramics are, therefore, bone-bonding [103] but their inherent brittleness and lack of toughness severely limits their applications.

4.3. Polymers

Because metals and ceramics are generally more rigid and hard than tissues, even bone, their use for tissue replacement or augmentation is counterintuitive. Polymers are preferred for these purposes because of their greater similarity to the natural structures. Furthermore, the wide variety of features, ranging from chemical reactivity to mechanical characteristics, that can be developed within the family of polymers, allows far better tailoring of these materials to meet precise specifications.

Polymers have the inherent capacity to display good biocompatibility since the macromolecules themselves are usually noncytotoxic. However, these macromolecules are very rarely used as the sole component of a material, most of which contains a variety of other substances, some desirable additives, other undesirable residues or contaminants, which tend to control biocompatibility. Plasticizers, antioxidants, residual monomers, and catalyst residues, for example, determine the properties. Polymers can be produced in a variety of forms ranging from elastomeric to rigid, cross-linked solids, from viscous resins to high molecular mass thermoplastics, by varying the molecular structure within the same chemical family.

Some of the major groups of biomedical polymers are listed below. These and other polymer families are described more fully elsewhere [104].

Polyethylene (→ Polyolefins) is, chemically, the simplest of all polymers. As a homochain polymer it is essentially stable and is suitable for long-term implantation in many situations. Moreover, it is amenable to a variety of production technologies, is relatively inexpensive, and has good mechanical properties, resulting in versatility with applications ranging from catheters to joint replacement. The latter is probably the most important and significant. After unsuccessful attempts with polymers that did not have adequate wear resistance, for example, PTFE, an ultrahigh molecular mass, high-density polyethylene became the material of choice for the acetabular component of hip replacements [105]. Although it does perform

adequately in many prostheses, wear does occur, and there is evidence now that if the wear rate exceeds a certain limit, the reaction to the wear debris will be destructive to the bone and will predispose it to failure [106].

Polypropylene (→ Polyolefins) is closely related to polyethylene, and has a similar versatility. Its medical uses range from high-strength, nondegradable sutures to the flexible integral hinges used in finger joint replacements.

Fluoropolymers (→ Fluoropolymers, Organic). The extreme inertness of some fluoropolymers is responsible for their widespread use, for example, polytetrafluoroethylene (PTFE). Unfortunately, the relatively poor mechanical properties limit their practical applications to softtissue reconstruction. There is no record of degradation of PTFE in the body, and tissue response to solid devices made of this material is minimal. Microporous expanded PTFE (Gore-Tex) is successfully used in small diameter artificial arteries [107], periodontal surgery, and other such applications.

Poly(methyl methacrylate) (PMMA) (→ Polymethacrylates) is a hard, brittle polymer that would appear to be unsuitable for most clinical applications. However, as well as being very resistant to degradation and well tolerated by tissues, it does possess two distinct advantages, which underpin many of its uses. Firstly, being an amorphous polymer it is transparent and is, therefore, the material of choice for most ophthalmological devices, especially intraocular lenses and hard contact lenses [108].

Secondly, it can be produced and fabricated under ambient conditions. It can be processed in dental laboratories which is crucial to its use in custom-made dental devices such as dentures and it may also be prepared intraoperatively, explaining its unique position as a bone cement which is made by mixing prepolymerized PMMA with monomeric methylmethacrylate, forming a dough [109]. This can be inserted into bone as a grout to hold a prosthesis firm within the bone. Although there are a number of deficiencies in this situation, including the release of heat associated with the polymerization process, the toxicity of the volatile methylmethacrylate, and the poor fracture toughness, no superior bone cement has been developed to date.

PMMA is the best known example of an acrylic polymer used in surgery but there are several derivatives of polyacids such as poly(acrylic acid) that are also employed. In particular, poly(hydroxyethyl methacrylate) is a crosslinked hydrogel that was developed specifically for use in contact lenses with the high oxygen permeability of its water-containing structure [110].

Polyesters (→ Polyesters) have a number of features which make them very attractive for medical use. The chemical structure of polyesters is intrinsically hydrolyzable so whether the polymer based on a specific polyester molecule is degraded or not will depend on the accessibility of the carboxyl groups to water.

Aliphatic polyesters based on naturally occurring substances such as lactic acid are *biodegradable*, with a combination of properties that render them highly suitable for transient functions in the body such as sutures or drug delivery systems. Since many polyesters are ideal for fabrication in the form of fibers, these materials, such as polyglycolic acid, polylactic acid, and polydioxanone, can be used as absorbable sutures. The precise molecular structure determines their rate of degradation and since the degradation products are natural and metabolizable, this process is generally well accepted [111].

The fiber-forming character of polyesters enables them to be prepared as *textiles*. Aromatic polyesters such as poly(ethylene terephthalate) (PET), are extensively used as the woven or nonwoven structures required in artificial arteries and ligament regeneration [112].

Polyurethanes (→ Polyurethanes) have had a very variable history of use in medical applications, partly arising from the wide range of materials that can be prepared with the urethane group. Bearing in mind the fact that the precursors of polyurethanes, such as toluene diisocyanate, have well-known toxicities, and the fact that the structures generally are susceptible to degradation, it is not surprising that these do display varying biocompatibility characteristics. Certain polyurethanes, however, have excellent mechanical properties, especially elas-

tomeric properties, which make them very suitable for areas of soft-tissue reconstruction. Polyurethanes also often have excellent blood compatibility. For these reasons, polyurethanes, especially polyether urethanes, have been used in critical blood-contacting applications, such as in the experimental implantable artificial heart [113]. They are also very suitable for catheters and similar devices.

However, their inherent susceptibility to degradation has resulted in a number of difficulties, for example, stress cracking of pacemaker lead encapsulation [114] and the degradation of porous coverings on breast implants [115]. The ideal characteristics, therefore, of elastic properties and blood compatibility needed for small diameter artificial arteries have yet to fully realized in devices of suitable long-term stability.

Silicones (→ Silicones, → Inorganic Polymers). Although the vast majority of synthetic polymers are based on the carbon – carbon bond, a small number are based on silicon. Linear chains of alternating silicon and oxygen atoms yield the family of siloxanes. Depending on the nature of the side groups attached to the silicon, the molecular size, and the degree of cross-linking, a range of substances may be produced, from oils to elastomers. It has long been thought that the inherent strength of the Si – O bond, coupled with the fact that this bond is not normally found in biological structures and should therefore be immune to enzyme-catalyzed degradation, should render it very stable. Thus, over several decades, substances such as polydimethylsiloxane have enjoyed widespread medical and dental use, ranging from elastomeric dental impressions to finger joint prostheses, catheters, intraocular oils, contact lenses, and a variety of soft tissue augmentation prostheses [116], [117].

However, the biocompatibility of silicones has been questioned [118], and claims have been made that silicones are capable of causing a wide variety of conditions, primarily autoimmune diseases. There is no clear evidence, but this matter is having a profound influence on the use of such materials in hitherto very common applications such as breast implants [119].

Natural Biopolymers. There is a trend toward the use of polymers derived from natural components where in some situations, the polymers themselves may be analogous to those occurring naturally.

Some tissues consist almost entirely of *collagen* and these may be used as biomaterials; one example is the tendon derived from the tails of certain animal species, for example, the kangaroo. Fortunately collagen is only a weakly antigenic protein and is unlikely to invoke an immune response when used in this way. It may be preferable, however, to prepare alternative forms of collagen, for example, by solubilization and reprecipitation. Some collagen products have quite widespread use in plastic surgery, although their stability is still questionable [120].

Hyaluronic acid is a polysaccharide that is widely distributed in tissues, especially in synovial fluid. It can be polymerized and modified in many ways resulting in a variety of degradable polymers with a number of potential applications [121].

4.4. Carbon

Carbon, as the major elemental constituent of organic molecules, would appear to be intrinsically safe to use within the body. On the basis of this putative inertness and biocompatibility, attempts have been made to use carbon, in several of its forms, as a biomaterial. Its major deficiency is that it is not a structural material and is difficult to fabricate into useful artifacts. As a bulk material it has very limited use; this can be seen by the attempts to use it in one of its few monolithic forms, as glassy carbon, in dental and other applications, the inevitable brittleness resulting in mechanical failures [122].

The interest in carbon is still intense but the forms in which it is used try to obviate these structural deficiencies. For example, it is used very successfully as a thin coating, in the form of pyrolytic graphite, deposited onto tough metallic substrates, for blood-contacting surfaces in heart valves [123]. An alternative carbon surface is the so-called diamond-like coating [124].

An alternative approach has involved the use of carbon fibers, well known for their intrinsic high strength and modulus of elasticity. Some applications have utilized tows or bundles of the fibers themselves, as with their use in artificial ligaments, but the majority are concerned with carbon compos-

ites, either carbon – carbon [125], carbon-fiber-reinforced thermosetting resins [126], or carbon-fiber-reinforced thermoplastics such as polyetheretherketone [127]. However, whilst chemically stable, the fibers themselves, by virtue of their tendency to fracture and produce small fragments of cellular dimensions, can be immensely irritating to tissues.

4.5. Composites

Attempts have been made to use composites in surgical materials, although up until now with limited success, since problems of biocompatibility have been aggravated through the increasing complexity of the structure.

There are several principles underlying the design of composites, usually mechanical in origin and commonly based upon maximizing fracture strength and optimizing elasticity. Strength is not usually markedly improved by the use of dispersed fibers or particles in a ductile plastic matrix, but it may be possible to achieve modest improvements. There is considerable scope for tailoring the elastic modulus by accurate control of components and their volume fractions. Although restorative dentistry has seen the development of a very successful range of particulate composites of quartz-like phases dispersed in dimethacrylate resin matrices [128], efforts with composite surgical materials have been far less successful. Apart from the carbon-fiber composites mentioned above, there have been unsuccessful attempts to strengthen bone cement by incorporating short fibers, and to improve the wear and creep resistance of polyethylene [129]. Especially disappointing has been the development of a carbon- or alumina-filled porous PTFE, intended as a prosthetic material to be replaced and incorporated into a variety of tissues [130].

4.6. Surface Modifications and Coatings

General Principles. Engineering materials used as structural components, with their surfaces modified to optimize biocompatibility is generally quite common. However, the varying requirements for biocompatibility and the need for long-term performance hinder their practical application as witnessed by the diverse and imaginative approaches already attempted.

Hard Coatings. Improving the hardness of a surface is thought to have a beneficial effect, not only when that surface is involved in a joint, but also when the release of any component through abrasion with tissue is possible. A variety of ionplating, ion-assisted deposition, ion-implantation, and other similar techniques may be employed [131].

Hydrophilic Coatings. Improved biocompatibility is thought to result if the surface is hydrophilic rather than hydrophobic. Such surfaces may be developed by grafting hydrogels onto polymer surfaces [132]. Better performance is likely when molecular species are grafted, in particular, when substances such as poly(ethylene glycol) are attached [133].

Pharmacological Coatings. In some circumstances it may be more appropriate to seek specific activity rather than passivity. One method would be to attach pharmaceuticals to surfaces, either by immobilizing them on the surface or incorporating them into the surface layer from which they may be released. This is most relevant in the case of blood-compatible surfaces, where anticoagulant, antiplatelet, fibrinolytic, or other agents may be attached to polymers (see Section 3.3.5).

Biomimetic Surfaces. The attachment of a layer of natural tissue-like material to engineering substrates may be difficult to imagine. One approach, however, involves biomimicry, the use of molecules that are analogous to components of tissue, which can behave as if it were that tissue. For example, phospholipids are the major molecular species of cell membranes and can be attached to a variety of substrates where, among other things, they substantially reduce the extent of protein adsorption. This is a particularly attractive property for contact lenses [134].

Cell seeding of biomaterial surfaces is of considerable interest; here it is often possible to render a surface attractive to a type of cell, for example, the endothelial cells that line blood vessels, and to incubate that material in a culture

of cells derived previously from the eventual recipient. If these cells are able to colonize the surface, then a pseudo-natural surface is generated. This technology is still under early stages of development but it is a very attractive solution to biocompatibility problems [135].

Hybrid Structures and Materials. Combinations of synthetic materials and natural components, either viable or nonviable, are now in experimental use. For example, the treatment of diabetes may be radically altered by the use of a primitive artificial pancreas, in which islets, the insulin-producing cells, are obtained from donors and encapsulated in membranes that allow the cells to respond to glucose levels and produce insulin, but protect them from the destructive proteins of the immune system [136].

1. Introduction

The term "intense sweeteners" is commonly used for substances that are much sweeter than sucrose, and which are either not metabolized in the human body or do not significantly contribute to the energy content of foods and beverages. Intense sweeteners may be produced synthetically or isolated from plants. Sucrose, related carbohydrates, and sugar alcohols should be clearly distinguished from intense sweeteners.

Plants containing sweet compounds have been used for centuries to sweeten foods and beverages, particularly in tropical countries, e.g., the thaumatin-containing plant, *Thaumatococcus daniellii* Benth [1].

The history of intense sweeteners began with the discovery of saccharin by C. Fahlberg and I. Remsen [2] in 1878. Fahlberg recognized the scientific and commercial importance of saccharin and took steps to market it; production commenced in 1884. Since then, many other sweet compounds have been discovered, mostly by chance. Only a very few of these compounds have been used as sweeteners in foods and beverages. Several substances have been withdrawn, owing to the emergence of toxicological problems or unsatisfactory properties.

Saccharin enjoyed great commercial success in periods of short sugar supply, e.g., during World Wars I and II. As a consequence, saccharin was considered a cheap and inferior sugar substitute. Taxes were imposed on saccharin to protect the sugar industry. Diabetics were the main consumers.

In the last three decades, the general perception of intense sweeteners has changed. The incidence of obesity, and increasing health-consciousness have paved the way for a more favorable attitude. The increasing importance of industrial food production, the need for systematic recipe development, and the resulting possibilities for large-scale production of products containing intense sweeteners has led to widespread availability of these products. Their main applications are no longer products especially intended for consumption by diabetics or people suffering from other metabolic disorders. Intense sweeteners are now rather used in products aimed at consumers interested in body weight management and a calorie-controlled diet.

The increasing demands on safety of food additives in general, and sweeteners in particular, resulted in a reevaluation and reassessment of the intense sweeteners commonly used until the 1960s. The results provoked an international discussion of their safety, which, in turn, stimulated an intensive search for alternative compounds with improved properties. Two of the sweeteners developed, acesulfame K and aspartame, have found widespread international approval, and others, such as thaumatin and neohesperidin dihydrochalcone are approved and used in some countries. More products are under evaluation (e.g., alitame) or about to enter the market (e.g., sucralose). There continues to be promising market opportunities for sweeteners with good taste, stability, and handling characteristics, but above all, a clean safety record.

2. Sensory Properties

2.1. Structural Requirements for Sweetness

The generally accepted theory for the phenomenon of sweetness was developed by Shallenberger and Acree [3]. According to this theory, a molecular system of a proton donor and proton acceptor is necessary, with a distance of ca. 0.3 nm between the groups. It is assumed that a component has a sweet taste whenever this so-called AH – B-system can interact with a complementary system located in the membrane of taste receptor cells.

Changes in the distance between groups, as well as changes in electronic structure influence the occurrence of the sweet taste, and may change the general taste perception, sometimes eliminating sweetness totally, or changing it to bitterness.

The AH – B-system (Fig. 1) is a necessary but not sufficient structural requirement for sweetness, and is therefore not a reliable indicator for its occurrence or absence. Accordingly, the molecular theory was extended to include a third binding site that interacts with the sweet receptor by hydrophobic contact; this model allows better correlation between molecular structure and sweetness [4].

Figure 1. Interaction of sweeteners and taste receptors [3] through the AH – B-system of saccharin

On the basis of intensive research on very sweet molecules, the number of potential interaction sites of sweetness receptors with sweetening agents has been extended to eight, two of which must be in contact with sweet molecules to elicit sweetness, and four have to be in contact for extremely intense sweetness [5].

More systematic approaches have sought to reveal the molecular structure of sweetness receptor molecules. These included structure – activity investigations in homologous series of sweet substances [6,7]. Investigations on nitroanilines, sulfamates, oximes, isocumarins, dipeptides, saccharins, acesulfames, chlorosugars, tryptophans, and ureas showed that, for certain substituents, an increase in chain length results in increased sweetness, but a sharp decrease to complete absence of sweetness was observed above the optimum. Similar observations were made for amino acid amides [8].

Superposition of different sweet compounds was used to identify structural requirements for the sweetness receptor molecules [9]. Assuming a peptide-based structure, interaction with the L-aspartyl-L-phenylalanine methyl ester with a helical peptide could be demonstrated, whereas the nonsweet D – D isomer was unable to form hydrogen bonds with this peptide [10].

It is still uncertain whether there is just one sweetness receptor with different binding sites, or several types of sweetness receptor with different response characteristics. It seems probable, however, that specific binding characteristics for different sweet tasting structures have to be assumed. A sweetness receptor model with binding sites for these structures has been suggested [11].

2.2. Sweetness Intensity

The sweetness intensity of a substance can be expressed in several ways. The sweetness intensity factor, or sweetness power, is most frequently used. It is the factor by which an equisweet sucrose concentration is more concentrated than a solution of the sweetener. Commonly used values are often based on comparison with 0.1 mol/L sucrose solutions, or solutions of similar concentration. Sweetness intensity factors compared with sucrose are given below:

Sweetener	Sweetness intensity
sucrose	1
sodium cyclamate	35
glycyrrhizin	50
stevioside	160
acesulfame K	200
aspartame	200
rebaudioside A	250
neohesperidin dihydrochalcone	330
sodium saccharin	450
saccharin	550
alitame	2500
thaumatin	3500

Sweetness intensities generally depend on the sweetener concentration and the sucrose concentration used for comparison. Therefore, values other than those given above may apply at lower or higher concentrations. A demonstration of this concentration dependence is given in Figure 2 (see next page) for some commonly used sweeteners. Estimates of use levels in foods and beverages are often possible on the basis of comparison tables of sweetness intensities [12].

Much higher sweetness intensity factors are observed at the taste threshold [12]. These values are sometimes reported, but are of no practical significance.

Apparently, maximal sweetness intensities exist for all sweet substances, above which an increase in concentration does not induce a higher sweetness perception. This property is well illustrated by graphs of equisweet solutions of sweeteners and sucrose (Fig. 3, see next page).

Determination of sweetness intensities requires sensory tests; panelists have to be used according to their sensory abilities, and to be adapted to the test procedures. Owing to individual variations in sweetness perception, results

have to be evaluated on a statistical basis [13, 14].

Figure 2. Sweetness intensity of saccharin (a), sodium saccharin (b), acesulfame K (c), and sodium cyclamate (d) compared with sucrose

Figure 3. Equisweet concentrations of acesulfame (– – –), aspartame (– · · –), sweetener blends and sucrose
Blend ratio: (–) 2:1; (· · ·) 1:2; (– · –) 1:1

2.3. Taste Characteristics

The taste quality of sweeteners depends on several characteristics in addition to sweetness. Time – intensity profiles of sweetness perception are important for the assessment of taste quality as well as the occurrence of side-tastes and aftertastes.

Temporal sweetness perception characteristics can be studied with modern sensory techniques [15–17]. As sucrose is not only the standard for sweetness intensity assessments, but also the ideal to be matched in other sensory characteristics, the time – intensity profile of sucrose is often considered the target. Lasting sweetness or delayed sweetness onset may impair the applicability of sweeteners. Time – intensity perception of sweetness is influenced by several substrate factors, e.g., viscosity, temperature, and the presence of taste-modifying compounds. Blending of sweeteners with different time – intensity profiles often results in a mixed profile, closer to that of sucrose.

The bitter aftertaste of saccharin is well known. As sweetness and bitterness are structurally closely related [9], bitter aftertastes are observed not only in some intense sweeteners, but also in a number of sweet carbohydrates. Individual susceptibilities for bitterness perception and taste thresholds vary. Off-taste thresholds as reported in water [18], however, give general information on taste characteristics of sweeteners rather than information on limitations of practical use, as interactions with food constituents may change taste perception substantially. Other off-tastes occurring in some intense sweeteners are menthol- or licorice-like tastes.

Taste modification of intense sweeteners has been widely studied in order to improve their sensory characteristics, especially time – intensity profiles, and reduce aftertastes. A wide variety of substances is claimed to have taste-modifying properties [19].

2.4. Synergism

In sweetener blends, synergistic sweetness enhancement is often observed (Fig. 4). Commonly used synergistic sweetener blends are acesulfame – aspartame, aspartame – saccharin,

and cyclamate – saccharin. The apparent intensification of sweetness compared with single sweeteners is not fully understood. Even definitions of the term "synergism" and methods for determination of synergistic effects vary [20–22]. For a number of combinations, calculation of equisweet concentrations on the basis of sweetness intensity data for single sweeteners seems possible [12]. In these cases synergism has to be regarded as the consequence of nonlinear sweetness response functions. For certain examples, e.g., acesulfame – aspartame blends, sweetness intensities calculated on the basis of the single sweetener response curves are below the observed values.

Figure 4. Equisweet concentrations of different levels of sucrose and acesulfame – aspartame blends
Sweetener blend, mg/L: (– –) 100; (· · ·) 200; (–) 300; (– · –) 400; (– · · –) 500

As time – intensity profiles of sweeteners are different, and often differ from the generally accepted standard sucrose, taste modifications can be achieved by blending; the resulting taste improvement is sometimes referred to as "qualitative synergism" [22].

When saccharin and cyclamate were generally available, blends of these two sweeteners were widely used. With the availability of acesulfame, aspartame, etc., synergism has attracted renewed interest, and blends of acesulfame – aspartame, aspartame – saccharin, and even tertiary or quaternary blends of sweeteners are increasingly used in order to exploit both types of synergism.

3. Uses

3.1. Foods and Beverages

Foods and beverages are the most important fields of application of intense sweeteners, with calorie reduction being the main goal. Single sweeteners or combinations with other sweet substances, e.g., carbohydrates, or sugar substitutes may be used. Intense sweeteners can be used in diabetic foods and beverages; depending on the type of product, either as single sweetening agents or combined with bulk sugar substitutes suitable for diabetic consumption (isomalt, lactitol, maltitol, mannitol, sorbitol, xylitol, etc.).

Whenever sugar and other sweet carbohydrates are used for their sweet taste, and not for functional reasons, replacement by intense sweeteners is generally simple. Functional sugar uses, such as viscosity enhancement, reduction of water activity, providing bulk, assistance in gelling, and others, cannot be provided by intense sweeteners owing to the minute concentrations used for normal sweetness levels. For foods requiring such functional properties, combinations of intense sweeteners and bulk sugar substitutes are an appropriate alternative whenever sugar or sweet carbohydrates are not to be used.

Beverage uses of intense sweeteners account for more than 50 % of human consumption; sugar replacement by intense sweeteners is simple, as carbohydrates do not play any important functional role in beverages, and the special taste characteristic commonly referred to as "body" can be achieved by addition of small quantities of sweet carbohydrates or viscosity-enhancing agents, such as certain polysaccharides.

Other important applications are fruit-flavored dairy products, desserts, etc.

In products such as pickles, marinated fish, and delicatessen salads, intense sweeteners not only round out the taste and balance the acidity, but also reduce the risk of spoilage (in contrast to sweet carbohydrates, they do not promote the growth of microorganisms).

In a number of applications, functional sweet carbohydrates are required for the specific product characteristics. For these applications, e.g., baked goods, confectionery products, and chewing gum, combinations of intense sweeteners

with bulk sugar substitutes or bulking agents are an alternative.

General information on applications is given in product-related brochures and some surveys [23–25].

3.2. Table-Top Sweeteners

For household use, intense sweeteners are formulated into table-top sweeteners, such as sweetener tablets, powders and spoon-by-spoon products, and liquids. Sweetener tablets may be produced as effervescent tablets containing a CO_2-releasing ingredient and an acid, such as sodium hydrogen carbonate and tartaric acid. Owing to the small amounts equivalent to a teaspoonful of sugar or a sugar cube, excipients, e.g., lactose or sugar alcohols, are often used for noneffervescent tablets.

For granular sweeteners, the same excipients or, if they are not intended for diabetics, glucose or sucrose are often used.

For spoon-by-spoon products, the bulk density of the granular product has to be reduced substantially; maltodextrins are most commonly used. To facilitate application of table-top sweeteners and to bring them close to standard sugar formulations, sugar-reduced cubes containing intense sweeteners with the same sweetness level as normal sugar cubes, and aqueous solutions of intense sweeteners, are also available.

3.3. Cosmetics

Several types of cosmetics, especially oral hygiene products, are sweetened to make them more pleasant for consumers. For oral hygiene products, noncariogenic ingredients have to be used. In dentifrices, polyols, such as glycerol or sorbitol, are used as humectants, and also provide some basic sweetness. The desired sweetness level is adjusted with an additional quantity of intense sweetener [26].

3.4. Pharmaceuticals

Intense sweeteners are used to mask undesired flavors and tastes of active pharmaceutical ingredients, e.g., bitterness, whenever the pharmaceuticals are intended for use by diabetics. Sweeteners are used in syrups, and soluble tablets and powders.

3.5. Feed

Intense sweeteners are used in animal feed to secure balanced nutrition. The main application is in starter feed for early weaning, in which intense sweeteners balance the palatability, and avoid decreased feed consumption immediately after weaning.

3.6. Others

Among other applications, tobacco and tobacco-related products are most important. In chewing tobacco, intense sweeteners are added to the flavoring systems. A further application is in cigarette tips, the palatability of which is improved by addition of intense sweeteners.

4. General Toxicology and Physiology

4.1. Toxicology

Intense sweeteners have to undergo the safety tests generally required for food additives, with long-term studies in at least two species, including a carcinogenicity study, mutagenicity studies in different test systems, studies on reproductive toxicity, pharmacokinetics, and metabolism.

Guidelines for these studies are available on an international and, in some countries, a national basis [27,28].

4.2. Metabolism

Most available intense sweeteners are not metabolized in the human body or they are excreted without metabolic utilization; they are therefore noncalorific. Some, especially peptide-based sweeteners, are digested and metabolized. In spite of this, these sweeteners are virtually noncalorific, as normal use levels are extremely low and the contribution to the nutritive value of foods and beverages is insignificant compared with nutritive bulk sweeteners.

4.3. Suitability for Diabetics

Intense sweeteners are metabolized independently of insulin, and therefore suitable for diabetics. Consumption of intense sweeteners in doses equivalent to a normal soft drink serving neither stimulates insulin secretion nor influences blood glucose levels [29].

4.4. Dental Effects

The commonly used intense sweeteners are not metabolized, or at least not into acids, by the bacteria of the oral cavity. They are therefore noncariogenic. Inhibitory effects on *Streptococcus mutans*, a caries-causing bacterium, have been demonstrated at sweetener concentrations above normal use levels. Synergistic enhancement of these effects in sweetener blends or blends of sweeteners and fluoride have also been demonstrated [30–32].

5. Food Legislation

5.1. International Regulations and Assessments

On the basis of available safety data, acceptability of intense sweeteners is assessed by several international authorities, especially the Joint Expert Committee on Food Additives of the WHO and FAO (JECFA), and the Scientific Committee for Food of the EU (SCF). JECFA bases a general evaluation on the available safety data. Acceptance for food use is demonstrated by allocation of an acceptable daily intake (ADI) value. The results of the evaluation are published as a toxicological monograph. In parallel, specifications are recommended which are normally used as guidelines for national food legislation. The SCF performs a similar evaluation, having produced a report on sweeteners in foods, and several subsequent publications [33].

Beyond national legislation, an EU directive on sweeteners harmonizes sweetener legislation in the Community, listing approved sweeteners, fields of application, and maximum use levels.

5.2. National Food Legislation

Under the food legislation of most countries, intense sweeteners are food additives, requiring approval for food use. Approvals are listed in national regulations, e.g., in the United States [34], the United Kingdom [35], and Germany [36].

6. Substances Commonly Used as Sweeteners

6.1. Acesulfame K

6.1.1. General Information

Acesulfame K was discovered by Clauss and Jensen during investigations on oxathiazinone dioxides. The sweet taste was found by chance [37, 38]. Several other oxathiazinone dioxides taste sweet, but have less favorable characteristics.

6.1.2. Physical and Chemical Properties

Acesulfame K is the potassium salt of 6-methyl-1,2,3-oxathiazin-4(3*H*)-one-2,2-dioxide (also 3,4-dihydro-6-methyl-1,2,3-oxathiazin-4-one-2,2-dioxide) [*55589-62-3*], $C_4H_4KNO_4S$, M_r 201.2.

Acesulfame K

Acesulfame K does not have a well-defined melting point, and starts decomposing at ca. 225 °C. It is soluble in water (ca. 270 g/L at 20 °C and ca. 1300 g/L at 100 °C). Solubility in most organic solvents is low. Aqueous solutions of acesulfame K are neutral [39].

At pH 3 – 7, the common range for most foods and beverages, acesulfame K is virtually stable. Losses of a few percent were reported only after prolonged exposure to lower pH [39, 40]. Acesulfame K does not decompose during normal processing conditions of foods and beverages. No decomposition was observed during baking

[41], ultra-high-temperature treatment [42], and microwave heating [43]. Hydrolysis in strong acids yields acetone, CO_2, and ammonium sulfate [44].

Figure 5. Synthesis of acesulfame K [37,46]

Compared with 3 % sucrose solution, the sweetness intensity of acesulfame K is approximately 200 [12]. An off-taste may become perceptible at elevated concentrations [18]. Acesulfame K is often synergistic with other sweeteners [45].

Figure 6. Synthesis of acesulfame K: alternative route [41, 48]

6.1.3. Production

Several synthesis routes for acesulfame K have been described. Potential synthesis starts from halogen sulfonyl isocyanates and keto compounds. Depending on the ketone, oxathiazinone dioxides with different substituents can be produced, some of which are also sweet, but inferior to acesulfame K in taste quality.

One production route (Fig. 5) starts from fluorosulfonyl isocyanate reacted with acetoacetic acid *tert*-butyl ester to a labile addition compound. On heating, this intermediate releases CO_2 and isobutene to form *N*-(fluorosulfonyl)acetoacetic acid amide; in the presence of bases, this compound cyclizes to the oxathiazinone dioxide ring [37,46].

An alternative synthesis route (Fig. 6) has been described in which diketene and amidosulfonic acid are reacted to acetoacetamide-*N*-sulfonic acid. In the presence of suitable dehydrating agents, acesulfame acid is formed, which can be neutralized with potassium hydroxide to acesulfame K [47,48].

6.1.4. Specifications and Analysis

For food use, acesulfame K has to conform to specifications laid down in national food legislation; these are often based on the suggestions made by JECFA [49], in which a purity > 99 % is required. Specific methods for the analysis of pure acesulfame K are given in these suggestions, and general methods are listed in a guide to the specifications [50].

Although several analytical methods for the quantitative determination of acesulfame K in foods and other products are available, HPLC analysis, allowing simultaneous determination of acesulfame K and other sweeteners, is often preferred [51,52].

6.1.5. Toxicology and Legislation

Acesulfame K has been subjected to the toxicological studies required for food additives. It is devoid of carcinogenicity, chronic toxicity, teratogenicity, and pharmacological side effects. It is absorbed quickly, and excreted at a similar rate, completely unmetabolized. Owing to the rapid excretion, accumulation in the body seems impossible. JECFA allocated an ADI of 0 – 15 mg/kg [53], as did the FDA [54].

Acesulfame K is approved for food use in most countries where intense sweeteners are used in foods and beverages, and is also approved for use in oral hygiene products and pharmaceuticals.

6.1.6. Uses

Acesulfame K is used in all fields of applications of intense sweeteners. Common applications are: table-top sweeteners; beverages; foods, such as dairy products, desserts, bakery products, confectionery, chewing gum, pickles, and marinated fish; oral hygiene products, such as tooth paste and mouthwash; and pharmaceuticals. Owing to its synergistic characteristics, acesulfame K is often used in sweetener blends, and in combination with bulk sweeteners in products requiring good stability, e.g., confectionery or bakery products [23, 40, 55].

6.2. Aspartame

6.2.1. General Information

The sweet taste of aspartame, *N*-L-α-aspartyl-L-phenylalanine methyl ester, was discovered by SCHLATTER [56, 57] in 1965, although the compound had been synthesized earlier. Systematic research on the sensory properties of dipeptide derivatives has revealed many sweet substances [58, 59].

6.2.2. Physical and Chemical Properties

Aspartame, [*22839-47-0*], $C_{14}H_{18}N_2O_5$, M_r 294.3 is a white crystalline powder virtually free from odor, with no well-defined melting point. At 196 °C itreacts to 5-benzyl-3,6-dioxo-2-piperazineacetic acid [*55102-13-1*] [60].

Aspartame

Solubility of aspartame in water depends on pH. At pH 5.2, the isoelectric point, solubility in water is approximately 1 g in 100 mL. With decreasing pH, solubility increases to a maximum value at pH 2.2. Water solubility also increases with temperature. In most organic solvents, the solubility is lower than in water [60].

At elevated temperature, solid aspartame slowly releases methanol to form aspartylphenylalanine and the dioxopiperazine. In aqueous solutions aspartame slowly hydrolyzes to amino acids and methanol; the dioxopiperazine can also be formed. The maximum stability in aqueous solution is at ca. pH 4. The rate of hydrolytic decomposition increases steeply with both increase and decrease of pH [60].

Aspartame stability studies have been carried out, e.g., in aqueous solutions [61, 62], beverages [63, 64], fruit preparations, yoghurt [65, 66], and under conditions favoring Maillard reactions [67]. Coating or encapsulation by cyclodextrins has been suggested to improve its stability [68].

Compared with 3 wt % aqueous sucrose solution, aspartame has a sweetness intensity of ca. 180 – 200 [12]. Its taste characteristics are generally assessed as good [18]. The sweetness perception can be slightly delayed and lasting [17].

6.2.3. Production

Production of aspartame normally starts from L-aspartic acid and L-phenylalanine or L-phenylalanine methyl ester. The production follows common routes of peptide synthesis, as the L-configuration of amino acids has to be retained (essential for sweetness).

Common production routes require protective groups for aspartic acid. The protective groups commonly used in peptide synthesis have been suggested for aspartame synthesis, but simple protection for large-scale production can be obtained by use of formylaspartic acid anhydride. It can be reacted with phenylalanine methyl ester to *N*-formylaspartame [69], from which the protective group has to be removed [70]. Especially simple production (Fig. 7, see next page) is possible from *N*-formylaspartic acid anhydride and L-phenylalanine. The resulting *N*-formylaspartylphenylalanine is treated with hydrochloric acid and methanol. The aspartame hydrochloride obtained can be crystallized for purification and transformed into aspartame after addition of a stoichiometric amount of a neutralizing agent [71, 72]. Adjustment of the solvent increases the yield by improving the ratio of α- to β-isomers [73]. Crystallization of

Figure 7. Synthesis of aspartame

α-aspartame hydrohalides is a suitable purification step, as β-hydrohalides are more soluble [74,75].

A commercially used alternative to chemical peptide synthesis is enzymatic formation of the peptide bond. Some proteinases, e.g., thermolysin, are able to catalyze peptide bond formation. Protected or nonprotected aspartic acid anhydride can be used. In contrast to chemical peptide bond formation, L-phenylalanine is selectively used from a racemic phenylalanine, and the remaining D-isomer can be racemized again [76].

6.2.4. Specifications and Analysis

National food legislation, for the use of aspartame in foods, is often based on the suggestions made by JECFA [77] in which a purity $> 98\,\%$ is required. Specific methods for the analysis of pure aspartame are given in these suggestions, and general methods are listed in a guide to the specifications [50]. Aspartame is also listed in the Food Chemicals Codex [78].

Although several analytical methods for the quantitative determination of aspartame in foods and other products are available, HPLC analysis, allowing simultaneous determination of aspartame and other sweeteners, is often preferred [51,52].

Methods allowing determination of aspartame and its breakdown products are available [61,63].

6.2.5. Toxicology and Legislation

Aspartame is devoid of carcinogenicity, chronic toxicity, and teratogenicity.

Being a dipeptide ester, aspartame is metabolized, with a nutritive value of 17 kJ/g (4 kcal/g); at normal use levels of several hundred milligrams per kilogram, this nutritive value has no practical importance.

JECFA allocated an ADI of 0 – 40 mg/kg [79], whereas the FDA value is 50 mg/kg [80].

Owing to its phenylalanine content, aspartame should be avoided by persons suffering from phenylketonuria, and a warning on aspartame-containing products is required in many countries.

Aspartame is approved for food use in most countries where intense sweeteners are used.

6.2.6. Uses

The sensory characteristics of aspartame allow its use in all common sweetener applications. Limitations are imposed by its susceptibility to hydrolytic decomposition, and limited temperature stability. The shelf life of aspartame-sweetened products with high water content has to be limited to periods in which no decrease in sweetness can be observed. No limitations exist for low-humidity products, unless they are exposed to high temperatures. Owing to the limited solubility of aspartame, preparations have been developed to facilitate dissolution [81].

Figure 8. Synthesis of cyclamates

In addition to single-sweetener applications, the synergistic properties of aspartame are used in a variety of blends.

Applications of aspartame in foods, beverages, and other products are described in surveys [24, 82].

6.3. Cyclamate

6.3.1. General Information

The sweet taste of salts of cyclohexylaminosulfonic acid was discovered accidentally by SVEDA in 1937 [83].

6.3.2. Physical and Chemical Properties

Cyclamates are salts of cyclohexylaminosulfonic acid (cyclohexylsulfamic acid) [*100-88-9*], $C_6H_{13}NO_3S$, M_r 179.2. Cyclohexylsulfamic acid melts at 169 – 170 °C, but its salts do not have well-defined melting points and decompose at elevated temperature. Cyclohexylaminosulfonic acid is less suitable for food use but is approved, like its sodium, potassium, and calcium salts [84, 85].

Cyclamates (M = e.g., Na, K, ½ Ca)

Sodium cyclamate, $C_6H_{12}NNaO_3S$, M_r 201.2 [*139-05-9*], is the most important cyclamate sweetener. It forms white crystals, decomposing at ca. 260 °C. Its solubility is 20 wt % in water at room temperature, whereas in most organic solvents solubility is low or extremely low [84, 85].

Calcium cyclamate [*5897-16-5*], $C_{12}H_{24}CaN_2O_6S_2 \cdot 2\,H_2O$, M_r 432.6, is of less importance. At pH 2 – 10, the stability of cyclamates to hydrolytic decomposition is high, so they are not affected by common food processing conditions [84, 85].

Compared with 0.1 mol/L sucrose solutions, the sweetness intensity of sodium cyclamate is ca. 35 [12]. Aftertastes become perceptible at elevated concentrations only, rendering cyclamate generally superior to saccharin [18].

6.3.3. Production

The starting material for cyclamate production is cyclohexylamine, which is reacted with sulfonating agents (Fig. 8) [86]. The originally used chlorosulfonic acid has been replaced by other compounds. In high-boiling-point solvents, cyclohexylamine reacts with sulfamic acid to *N*- cyclohexyl-*N*- cyclohexylammonium sulfamate. Reaction with sodium or calcium hydroxide yields cyclamates and free cyclohexylamine. In a corresponding way, equimolar amounts of cyclohexylamine and tertiary amines react to trialkylammonium-*N*- cyclohexyl sulfamates, the respective cyclamates being formed after reaction with sodium or calcium hydroxide. Further possibilities are reactions of cyclohexylamine with sodium methylthiosulfate or sulfamic acid metal salts. Reactions of cyclohexyl compounds with SO_3 or sulfuric acid, or of cyclohexylhydroxylamine and SO_2 or sulfites, producing cyclamates or cyclohexylsulfamic acid have also been described [87, 88].

6.3.4. Specifications and Analysis

The suggestions made by JECFA for cyclamates in foods [89] require a purity > 98 %. Specific methods for the analysis of pure cyclamate are given in these suggestions, and general methods are listed in a guide to the specifications [50].

Owing to the absence of a chromophore for UV detection, analytical methods for cyclamates have to be based on either color changes or

other properties. A suitable HPLC method with post-column derivatization for easy detection has been described [90].

6.3.5. Toxicology and Legislation

Reevaluations of toxicological data have concluded that cyclamates are devoid of carcinogenicity. Discussion focused on the toxicity of cyclohexylamine, a potential metabolite formed by intestinal bacteria [91]. Current ADI values are based on the toxicity data for cyclohexylamine, and the assumption of a fairly high metabolic rate in the human body. Both JECFA and SCF allocated ADI values of 0 – 11 mg per kilogram body weight [33, 92].

Whereas some countries approve cyclamate use in a variety of applications, some important sweetener markets, such as the United States, still ban them.

6.3.6. Uses

Owing to their good stability, cyclamates are suitable for all applications of intense sweeteners. They can be used in acid products, e.g., soft drinks and pickles, and withstand exposure to elevated temperature as used in the production of canned fruit [85].

The main application of cyclamates, however, is in blends with saccharin in a 10:1 ratio by weight. In these blends, quantitative and qualitative synergistic effects can be used to advantage, rendering them an important sweetener system in countries approving the use of both sweetenes [85].

6.4. Saccharin

6.4.1. General Information

Saccharin was the first intense sweetener ever introduced. It was discovered in 1878 [2]. Small-scale production commenced in 1884, and it has been available since. For decades, saccharin was the most important intense sweetener.

6.4.2. Physical and Chemical Properties

Saccharin, often referred to as *o*-benzoic acid sulfimide, or *o*-sulfobenzoic acid imide, is 1,2-benzisothiazol-3(2*H*)-one-1,1-dioxide [*128-44-9*], $C_7H_5NO_3S$, M_r 183.2. Solid saccharin is a white, crystalline, odorless powder, melting at 228 – 230 °C. Solubility in water at 20 °C is ca. 2 g/L and increases to ca. 40 g/L at 100 °C. Aqueous solutions of saccharin are acidic, pH ca. 2 for a saturated solution at room temperature. In aqueous solutions of alkali hydroxides or carbonates, saccharin is easily soluble, forming salts [93].

The sodium salt is more important than saccharin itself. Sodium saccharin [*6155-57-3*], $C_7H_4NNaO_3S \cdot 2\,H_2O$, M_r 241.2, crystallizes with water of crystallization. Commercial preparations, however, may not contain the stoichiometric water content, but a slightly lower value. In contrast to saccharin itself, sodium saccharin is soluble in water. At room temperature, ca. 1000 g can be dissolved in 1 L of water, and more than 3000 g dissolve in 1 L of water at 100 °C [93].

Calcium saccharin, $C_{14}H_8CaN_2O_6S_2 \cdot 31/2\,H_2O$, M_r 467.5 [*6381-91-5*], is of less importance than sodium saccharin. At 20 °C, ca. 370 g can be dissolved in 1 L of water, but at 100 °C solubility is almost as high as for sodium saccharin [93].

Saccharin

Compared with dilute sucrose solutions, the sweetness intensity of saccharin is ca. 550, whereas the values for its salts are ca. 450 [12]. At medium or elevated use levels, saccharin sweetness is accompanied by a metallic or bitter aftertaste [18]. Several masking agents for this side-taste have been suggested, and sweetener blends, especially a blend of 1 part sodium saccharin to 9 – 10 parts sodium cyclamate, are often used [94].

6.4.3. Production

In most countries, commercial saccharin is produced by the Remsen – Fahlberg process (Fig. 9), which basically follows the synthesis

described by its discoverers [95,96]. Toluene is used as the starting material and reacted with chlorosulfonic acid to a mixture of isomeric toluene sulfochlorides. In the presence of ammonia, 2-toluene sulfochloride forms 2-toluene sulfonic acid amide which is oxidized under appropriate conditions to saccharin. Potential oxidizing agents are potassium permanganate or chromic acid; syntheses not involving oxidizing agents have also been described [97].

Figure 9. Remsen – Fahlberg synthesis of saccharin [96]

In the United States, the Maumee process is used (Fig. 10). This starts from either anthranilic acid or its methyl ester, which can be obtained from phthalic acid anhydride. With sodium nitrite, anthranilic acid forms a diazonium compound, which is reacted with sulfur dioxide or sulfites, and chlorinated to 2-chlorosulfonylbenzoic acid methyl ester. In the presence of ammonia, this ester yields the respective amide, from which, after de-esterification, saccharin is obtained. Reaction with sodium hydroxide or calcium hydroxide forms the respective saccharin salts [98].

Figure 10. Maumee synthesis of saccharin [98]

6.4.4. Specifications and Analysis

The suggestions made by JECFA [99] for saccharin in foods require a purity > 99 %. Specific methods for the analysis of saccharin and saccharin salts are given in these suggestions, and general methods are listed in a guide to the specifications [50]. Saccharin and its sodium and calcium salts are also listed in the Food Chemicals Codex [98].

Although several analytical methods for the quantitative determination of saccharin and sodium saccharin in foods and other products are available, HPLC analysis, allowing simultaneous determination of saccharin, sodium saccharin, and other sweeteners, is often preferred [51,52].

6.4.5. Toxicology and Legislation

Saccharin is not metabolized in the human body. It is without influence on diabetics. Safety studies on saccharin have been repeatedly performed. In long-term feeding studies in rats an increased bladder tumor rate was observed after prolonged ingestion of high doses. This was attributed to a nongenotoxic action of saccharin, or to a co-carcinogenic effect. On the basis of further studies, the relevance of these observations for humans has been questioned. Information on saccharin toxicology has been reviewed [100]. JECFA allocated an ADI of 0 – 5 mg/kg [101].

Saccharin use is restricted in several countries, although in most countries it is still available as an intense sweetener. In the United States, a special label is required for saccharin-sweetened products [102].

6.4.6. Uses

Saccharin is most frequently used as its sodium salt. Important fields of application are soft drinks, table-top sweeteners, and desserts. For taste reasons, blends with other intense sweeteners, or combinations with reduced sugar levels are preferred wherever such blends are approved. In oral hygiene products, e.g., toothpastes and mouthwashes, saccharin masks undesired tastes of other ingredients [93].

In starter feed for livestock, saccharin is used to avoid reduced feed intake after weaning.

Beside its applications as an intense sweetener, saccharin is used in electrolytic nickel deposition. Addition of saccharin to the nickel salt solutions increases the hardness and brightness of the nickel plate. This effect is apparently specific to saccharin [93].

7. Sweeteners of Lesser Importance

7.1. Glycyrrhizin

7.1.1. General Information and Properties

Glycyrrhizin is the name for mixed calcium and potassium salts of glycyrrhizic acid which are found in licorice root, *Glycyrrhiza glabra* L., grown in Southern Europe and Asia.

Glycyrrhizic acid [*1405-86-3*], $C_{42}H_{62}O_{16}$, M_r 823.0, is a glycoside, consisting of glycyrrhetic acid, a triterpene of the β-amyrine type, and two β-1,2-glycosidic-linked glucuronic acids. Extracts containing 6 – 14 % glycyrrhizinates are available as licorice. It is used as a flavoring ingredient in confectionery and pharmaceuticals [103].

Glycyrrhizic acid

In addition to calcium and potassium glycyrrhizinates, crude ammonium glycyrrhizinate and monoammonium glycyrrhizinate are available. Ammonium glycyrrhizinate dissolves in water above pH 4.5, and in aqueous ethanol, but the solubility of monoammonium glycyrrhizinate in water is fairly low. At elevated temperature, glycyrrhinates are not fully stable to hydrolytic decomposition [103].

Glycyrrhizin is claimed to be 50 – 100 times sweeter than sucrose in dilute aqueous solution, whereas for ammonium glycyrrhizinate the sweetness intensity is ca. 50. Glycyrrhizinates are characterized by a delayed sweetness onset, a lingering sweetness, and a pronounced licorice taste; they are therefore considered to be flavorings rather than sweeteners [103].

7.1.2. Production

The starting material for the production of glycyrrhizin is dried, cut licorice root, with a glycyrrhizin content of 2 – 7wt %, depending on its origin. A crude extract is obtained by countercurrent extraction with water. After removal of polysaccharides, glycyrrhizic acid can be precipitated from the crude extract with sulfuric acid. Ammonium glycyrrhizinate is produced by dissolving crude glycyrrhizic acid in aqueous ammonia, and subsequent drying or precipitation with ethanol. Repeated recrystallization yields monoammonium glycyrrhizinate which, in contrast to the dark colored ammonium glycyrrhizinate, is almost colorless [103].

7.1.3. Toxicology and Legislation

Glycyrrhizin is characterized by a variety of physiological activities, which discourage the use of large quantities for sweetening purposes. Accordingly, it is not approved as a sweetener in many countries, but can be used as a licorice flavoring agent.

7.1.4. Uses

In addition to their flavoring properties, glycyrrhizin and ammonium glycyrrhizinate have flavor-enhancing effects in certain products. Important fields of application are confectionery, soft drinks with higher pH levels, tobacco products, and oral hygiene products [103].

Extracts of licorice root, glycyrrhizin, and glycyrrhizic acid have been suggested for treatment of a number of diseases, e.g., gastric ulcer [104].

7.2. Neohesperidin Dihydrochalcone

7.2.1. General Information and Properties

Neohesperidin dihydrochalcone, 2′,3,4′,6′-tetrahydroxy-4-methoxydihydrochalcone-4′-β-neohesperidoside [*20702-77-6*], $C_{28}H_{36}O_{15}$, M_r 612.6 is the important compound among the sweet dihydrochalcones. A number of related dihydrochalcones, e.g., naringin dihydrochalcone, are without practical importance.

Neohesperidin dihydrochalcone

Neohesperidin dihydrochalcone has a melting range of 152 – 154 °C. In water only ca. 0.5 g/L dissolves at room temperature, but much higher quantities can be dissolved at high temperature and in ethanol (ca. 20 g/L). In alkaline solution, dissolution is favored owing to salt formation [105].

Despite the possibility of hydrolytic cleavage of the glycosidic bond, the stability of neohesperidin dihydrochalcone is acceptable under food processing and storage conditions [105].

Compared with dilute sucrose solutions, the sweetness intensity of neohesperidin dihydrochalcone is ca. 330. The much higher values sometimes reported were determined at the taste threshold. Neohesperidin dihydrochalcone is characterized by a pronounced menthol-like aftertaste which limits its applicability and allows it to make only a partial contribution to the total sweetness of most products [105].

Neohesperidin dihydrochalcone can be analyzed by HPLC [106].

7.2.2. Production

Neohesperidin dihydrochalcone is obtained by hydration of neohesperidin under alkaline conditions. This compound can be isolated from the skins of Seville oranges. A further production route starts from naringin (Fig. 11), found in the skins of several other citrus species. Treatment of naringin with alkali produces phloroacetophenone-4′-β-neohesperidoside which is condensed with isovanillin to neohesperidin chalcone. Hydrogenation under alkaline conditions yields neohesperidin dihydrochalcone [107, 108].

Figure 11. Synthesis of neohesperidin dihydrochalcone, starting from naringin

7.2.3. Toxicology and Legislation

Neohesperidin dihydrochalcone has been tested in a full range of safety studies, and an acceptable daily intake value of 0 – 5 mg per kilogram body weight was allocated by SCF [109]. Approval of this sweetener is limited to few countries, e.g., those in which it can be produced from the skin of citrus fruits. Extension of approval seems possible.

7.2.4. Uses

The specific taste characteristics of neohesperidin dihydrochalcone limit its use to few applications, or low use levels. It acts synergistically with a number of other sweeteners, e.g., acesulfame and aspartame, and can be used in fairly small quantities in blends with these sweeteners. The main fields of application are certain confectionery products and chewing gum, but small concentrations are suitable for use in beverages and dairy products. In addition to sweetness, neohesperidin dihydrochalcone

has flavor-enhancing properties in a variety of foods and other products [105].

7.3. Stevioside and Rebaudioside

7.3.1. General Information and Properties

Stevioside and other steviol glycosides are constituents of the South American plant *Stevia rebaudiana* Bertoni. It is claimed that the leaves of the plant have been used for centuries to sweeten foods and beverages.

Stevioside is a glycoside consisting of the aglycone steviol, *ent*-13-hydroxykaur-16-en-19-oic acid, and three glucose molecules, two of which are linked to the disaccharide sophorose. Stevioside is therefore named as 13-*O*-β-sophorosylsteviol-18-*O*-β-glucosyl ester [*57817-89-7*], $C_{38}H_{60}O_{18}$, M_r 804.9.

Stevioside

Beside steviol, the leaves of *Stevia rebaudiana* contain a number of other sweet glycosides, the most important of which is rebaudioside A. Rebaudioside A is 13-*O*-β-glycopyranosylsteviol-19-*O*-β-glucopyranosyl-(1,3)-sophorosyl ester [*58543-16-1*], $C_{44}H_{70}O_{23}$, M_r 967.0. Further sweet constituents of *Stevia* leaves are other steviol glycosides, such as other rebaudiosides, dulcoside, and steviolbioside.

Stevia originates in South America, but is also grown in several Asian countries. Dried *Stevia* leaves contain 2 – 22 wt % of stevioside with a mean of ca. 7 %. Rebaudioside levels are in the range 1.5 – 10 % [110].

Stevioside melts in the range 196 – 198 °C. The solubility in water is approximately 1.2 – 1.3 g/L, only slightly higher than the concentrations necessary for medium or high sweetness. Stevioside is of acceptable stability for food production and storage, e.g., for use in soft drinks. At elevated temperature, the stability decreases with decreasing pH [111].

Compared with dilute sucrose solution, stevioside is ca. 160 – 170 times sweeter. The higher sweetness intensity values often reported were determined at the taste threshold. The sweetness of stevioside is accompanied by a licorice-like aftertaste. Side-tastes and other sensory characteristics depend on the decomposition of stevioside products which are often purified extracts containing other plant constituents in addition to stevioside [112].

Rebaudioside A melts in the range 242 – 244 °C. In water, itis more soluble than stevioside. Although the stabilities of steviosides and rebaudioside A are similar, rebaudioside A has been found to decompose on exposure to light [111].

The sweetness intensity of rebaudioside A is approximately one-third higher than that of stevioside, and its taste characteristics are superior [110].

7.3.2. Production

Stevioside can be isolated from the leaves of *Stevia* by extraction with water or water – ethanol mixtures. Crude *Stevia* extracts are more or less purified, e.g., by treatment with calcium or magnesium hydroxides or carbonates. Further purification by ion-exchangers, or absorption of undesired ingredients is possible. Stevioside can be obtained from the extracts by precipitation with methanol [112].

Depending on the processing conditions, stevioside products may contain other sweet steviol glycosides, and other constituents. Accordingly,

the properties of commercially available stevioside products vary.

Rebaudioside A is isolated from *Stevia* leaves in a similar way to stevioside. The ratio of rebaudioside A to stevioside can be increased by extraction with methanol, and further purification with column chromatography yields rebaudioside-A-rich products. Stevioside can, in addition, be transformed enzymatically to rebaudioside A [110].

Commercial production routes often fail to yield pure stevioside or rebaudioside A.

7.3.3. Toxicology and Legislation

Although safety studies on stevioside and rebaudioside have been performed, they have not been accepted internationally, owing to the lack of generally accepted specifications. Accordingly, no ADI has been allocated for these compounds on an international basis. *Stevia* extracts are approved for food use in several South American and Asian countries, but lack approval in Europe and North America [110, 111].

7.3.4. Uses

Stevioside, the more important product, is used in table-top sweeteners, confectionery, certain soft drinks, fruit products, and Japanese-style vegetable products in countries approving the sweeteners, generally as stevioside-rich *Stevia* extracts.

7.4. Sucralose

7.4.1. General Information and Properties

Sucralose is the common name for 1′,6′-dichloro-1′,6-dideoxy-β-D-fructofuranosyl-4-chloro-4-deoxy-α-D-galactopyranoside, sometimes referred to as trichlorogalactosucrose.

The sweetener was discovered in 1976 [113]. Following the discovery that halogenation increases the sweetness of carbohydrates substantially, several chlorinated and brominated mono- and disaccharides of intense sweetness were found.

Sucralose

Sucralose [*56038-13-2*], $C_{12}H_{19}O_8Cl_3$, M_r 397.6. The solubility in water is ca. 283 g/L at 20 °C and ca. 90 g/L in ethanol [114]. Sucralose melts at 125 °C with decomposition.

Solid sucralose is not fully stable, and slowly releases HCl, with discoloration. In contrast, aqueous solutions are highly stable, and it is marketed in this form. Owing to its stability over the normal pH range of foods and beverages, it is suitable for all liquid sweetener applications [115].

Compared with dilute sucrose solution, sucralose is ca. 600 times sweeter. The sweetness is

Figure 12. Synthesis of sucralose
Trt = Ph_3C = trityl group

perceived with a slight delay and a lasting effect, similar to aspartame, and generally considered of good quality.

7.4.2. Production

The starting material for the synthesis of sucralose (see Fig. 12) is sucrose. The production route commonly described blocks the three primary hydroxyl groups as trityl ethers, and transforms the secondary hydroxyl groups to acetates to yield 6,1′,6′-tritrityl-2,3,4,3′,4′-pentaacetylsucrose. By deblocking the primary hydroxyl groups, 2,3,4,3′,4′-pentaacetylsucrose is obtained. Under appropriate conditions, this compound can be transformed to 2,3,6,3′,4′-pentaacetylsucrose. Chlorination at the exposed hydroxyl groups gives 4,1′,6′-trichloro-4,1′,6′-tridesoxygalactosucrose on conversion of the glucose moiety to galactose. Removal of the acetate groups by hydrolysis yields sucralose. Other blocking agents have also been described [116].

7.4.3. Toxicology and Legislation

Sucralose has been studied in the test systems commonly used for the evaluation of food additives. JECFA allocated an ADI of 0 – 15 mg/kg [117]. Sucralose has not yet been endorsed by other international authorities, and still lacks approval in most countries.

7.4.4. Uses

Owing to the lack of approval, sucralose uses are limited. Its good stability is considered an incentive for single sweetener use, which appears feasible on the basis of its sensory characteristics, but its synergistic characteristics probably favor its use in blends.

7.5. Thaumatin

7.5.1. General Information and Properties

Thaumatin is a mixture of structurally related proteins found in the arils of the fruits of *Thaumatococcus daniellii* Benth, a plant originating in West Africa, where it is grown on plantations. The sweet taste of *Thaumatococcus* fruits, locally called Katemfe and traditionally used for sweetening purposes, was first described in the scientific literature in 1855 [1].

Thaumatin consists of several structurally related polypeptides with approximate M_r 21 000 [*53850-34-3*]. Normally, thaumatin I and II are the major components, but other similar peptides may be present in thaumatin products. The amino acid composition and tertiary structure are known [118, 119].

Thaumatin is highly soluble in water, and solutions containing more than 1000 g of thaumatin in 1 L of water can be prepared [120]. Thaumatin stability data in the literature are not consistent. Good stability below pH 5.5 has been claimed, but limited stability is also reported [120].

Compared with dilute sucrose solutions, thaumatin is approximately 3500 times sweeter. The sweetness shows a delayed onset and long persistence, accompanied by a licorice-like sidetaste. Thaumatin is often used as a flavor enhancer rather than as a sweetener [120].

7.5.2. Production

Thaumatins are extracted from the arils of *Thaumatococcus* with water; removal of solids is by centrifugation and ultrafiltration. Further purification is possible by ion-exchange chromatography [120].

As production of thaumatin in countries growing *Thaumatococcus* is difficult, attempts have been made to produce thaumatin by means of genetically engineered microorganisms. Expression of the thaumatin genes in several microorganisms has been achieved, but no biotechnological production has yet been established [121, 122].

7.5.3. Toxicology and Legislation

Thaumatin is digested like other peptide food constituents. No effects of toxicological significance have been observed in safety studies on thaumatin. It has been accepted internationally as a food additive by JECFA [123], with ADI "not specified". It is approved as a sweetener and flavor enhancer in a number of countries.

7.5.4. Uses

Although thaumatin was primarily introduced as a sweetener, the temporal sweetness characteristics do not favor its use as a single sweetener, and limit blend use to fractions of the total sweetness.

Flavor-enhancing properties, in contrast, are of some importance; thaumatin is used as a flavor enhancer in confectionery, chewing gum, and similar products [120].

8. New Developments

8.1. Alitame

Alitame, L-α-aspartyl-*N*-(2,2,4,4-tetramethyl-3-thietanyl)-D-alanine [*80863-62-3*], $C_{14}H_{24}O_4N_3S \cdot 21/2\,H_2O$, M_r 375.3, is an intensely sweet dipeptide derivative [124].

Alitame

Alitame melts at 100 °C, solidifies at 102 °C, and starts decomposing at 136 – 137 °C. At room temperature, ca. 130 g/L can be dissolved in water at pH 5.0, with increasing solubility at higher and lower pH, and higher temperature [125].

Being a dipeptide, alitame is not completely stable, but superior to aspartame at all important pH levels, especially in the neutral range.

Compared with dilute sucrose solutions, its sweetness intensity is > 2500. Sensory properties are similar to aspartame.

Alitame is under safety evaluation and has not been endorsed as a food additive by international authorities, nor yet approved in most countries [125].

8.2. Others

Systematic investigations into structure – activity relationships of sweeteners have led to a variety of products with sweetness intensities comparable to the sweetest products already known, or even higher. A number of products have been described, e.g., derivatives of *N*-phenylguanidinoacetic acid and *N*-phenylethanamidinoacetic acid [126, 127], tetrazole derivatives [128], or amide-, glycine- and β-alanine-based sweeteners with heterocyclic substituents [129]. These products are still far from being marketed, although some are apparently under safety investigation for human consumption.

Monellin is a polypeptide constituent of the fruits of *Dioscoreophyllum cumminsii* Stapf Diels, with approximate M_r 11 500. The yield from 1 kg of fruitis ca. 3 – 5 g [130, 131]. Its sweetness intensity is ca. 2000. Owing to its structure, monellin is sensitive to conformational changes caused by heat or hydrolytic decomposition, rendering it unsuitable for normal sweetener use. As monellin is intensely sweet, and has a pleasant taste, studies have been initiated to improve the stability by structural changes, without impairing the good sensory characteristics.

9. Substances Formerly Used as Sweeteners

9.1. Dulcin

Dulcin is the common name of *N*-(4-ethoxyphenyl)urea [*150-69-6*], $C_9H_{12}N_2O_2$, M_r 180.2. Dulcin melts at 173 °C and is sparingly soluble in water (ca. 1.25 g/L). Compared with dilute sucrose solutions, it is approximately 250 times sweeter. Sweetness characteristics are good.

Dulcin

Dulcin was synthesized by reaction of phenetidine hydrochloride with sodium cyanate or urea, and by reaction of 4-phenetidine with phosgene and ammonia [132, 133]. Dulcin achieved some practical importance as a sweetener, despite safety concerns. It was blended with saccharin or sodium saccharin in order to mask the aftertaste of saccharin. As some dulcin metabolites were considered potentially hazardous, it is now banned in most countries.

9.2. Others

Suosan is the common name for the sodium salt of *N*-(ethyl)-*N*-(4-nitrophenyl)urea, $C_{10}H_{10}N_3NaO_5$, M_r 275.2 [134]. Pure suosan is a yellow crystalline substance ca. 300 times sweeter than sucrose in dilute solutions. It can be obtained by reacting 4-nitrophenyl isocyanate and β-alanine.

For some time, the sodium salt of *2-(4-methoxybenzoyl)benzoic acid*, $C_{15}H_{11}NaO_4$, M_r 278.3 [135], was offered as the product S 23/46. This substance is ca. 150 times sweeter than sucrose, but is bitter at elevated concentrations. Low solubility of the corresponding acid, which is released in acid foods and beverages, limited the applicability. The compound was synthesized from phthalic acid anhydride and anisole in the presence of aluminum chloride.

Several substituted nitroanilines are distinguished by high sweetness intensity. The sweetest compound in this group is *2-propoxy-5-nitroaniline*, $C_9H_{12}N_2O_3$, M_r 196.3, which is ca. 4000 times sweeter than sucrose. Attempts to market this product, as Ultrasüß or P 4000, were unsuccessful, owing to unsatisfactory sensory properties. It was synthesized by reaction of 1-chloro-2,4-dinitrobenzene and sodium propylate, with subsequent partial reduction, or by reaction of 2-nitrophenol with 1-chloropropane, reduction of the intermediate to the amino compound, and subsequent nitration [135]. *Perillatine*, the *E*-oxime of 4-(2-propenyl)-1-cyclohexene carboxaldehyde, $C_{10}H_{15}NO$, M_r 165.2, commonly called perilla aldehyde, was marketed for a time in the United States. The product is ca. 2000 times sweeter than sucrose, but has less than satisfactory sensory characteristics [136].

Sympatholytics and Sympathomimetics

Sympatholytics and sympathomimetics act on the sympathetic nervous system (→ Neuropharmacology, Chap. 3.1., → Neuropharmacology, Chap. 5.3.3.). Sympatholytics are blocking (antagonist), sympathomimetics, stimulant (agonist) drugs. They are subdivided into α_1, α_2, β_1, and β_2 agents according to the receptor types that they affect.

Sympatholytics are known as adrenergic blockers since they inhibit the stimulatory (adrenergic) effects of norepinephrine (noradrenaline) and epinephrine (adrenaline) by blocking the corresponding receptors.

α-Sympatholytics are vasodilatory and they thus lead to a lowering of the blood pressure. α_1-Drugs that selectively block the α_1-adrenoceptors, such as prazosin [*19216-56-9*], indoramin [*26844-12-2*], and urapidil [*34661-75-1*], are effective in the treatment of hypertension (→ Antihypertensives, Chap. 4.2.2.).

β-Sympatholytics are a widely used class of drugs that reduce heart rate by blocking cardioaccelerator receptors, and lower blood pressure by a mechanism that is not entirely clear. The most commonly used drug of this class is propranolol [*525-66-6*], which blocks both β_1- and β_2-receptors. It is used in the treatment of coronary heart disease, hypertension, and cardiac arrhythmias and other conditions (→ Coronary Therapeutics, Chap. 4.; → Antihypertensives, Chap. 4.2.3.; → Antiarrhythmic Drugs,→ Antiarrhythmic Drugs, Chap. 2.2.). Other important β-sympatholytics are metoprolol [*37350-58-6*], nadolol [*42200-33-9*], pindolol [*13523-86-9*], timolol [*26839-75-8*]. Timolol is also used as eye drops in the treatment of glaucoma (→ Ophthalmological Preparations, Chap. 5.2.). For further information, see → β-Receptor Blocking Agents.

Sympathomimetics, also called adrenergic drugs, act on the sympathetic nerves in the same way as norepinephrine and epinephrine (→ Hormones, Chap. 2.2.). The action of α-sympathomimetics corresponds to that of norepinephrine, resulting in vasoconstriction and increased peripheral resistance and blood pressure. They include hypertensive drugs such as norfenefrine [*536-21-0*].

The stimulation of β_1-receptors leads to increased heart rate and cardiac output, whereas the stimulation of β_2-receptors causes relaxation of smooth muscle, e.g., vascular and bronchial. Sympathomimetics stimulating both α- and β- receptors are commonly employed to raise blood pressure (→ Antihypotensives, Chap. 2.) and there is limited application in the short-term treatment of heart failure (e.g., dopamine [*51-61-6*], dobutamine [*34368-04-2*]). The cardiac glycosides and synthetic cardiotonic drugs act by different mechanisms to stimulate the heart (→ Cardiac Glycosides and Synthetic Cardiotonic Drugs, Chap. 3.1.). β_2-Sympathomimetics (e.g., fenoterol [*13392-18-2*]) cause bronchodilation and are used in the treatment of asthma (→ Antiasthmatic Agents, Chap. 2.1.).

Sympathomimetics are also used as mydriatics to dilate the pupil of the eye for diagnostic purposes (→ Ophthalmological Preparations, Chap. 6.1.) and in the treatment of glaucoma (→ Ophthalmological Preparations, Chap. 5.1.).

A distinction is made between indirectly acting and centrally acting sympathomimetics. Indirectly acting sympathomimetics, e.g., stimulants such as amphetamines, ephedrine, and cocaine, release norepinephrine from sympathetic nerve endings. Centrally acting α-sympathomimetics, such as clonidine [*4205-90-7*] and methyldopa [*555-30-6*], cause stimulation of α_2-adrenoreceptors in the central nervous system which, in contrast to stimulation of reception in blood vessels, leads to a fall in blood pressure (→ Antihypertensives, Chap. 4.1.1., → Antihypertensives, Chap. 4.1.2.).

1. Talc

1.1. History

Talc, soapstone, and steatite have been used by humans as raw materials since prehistoric times. Molds carved from soapstone were used in the Bronze Age and early Iron Age for casting weapons and tools. In the Mediterranean cultures of the classical period, stone carvings were made from soapstone, and talc was used for treating wounds and in the production of cosmetic powder. In ancient Rome, women used large amounts of powder and rouge. The properties of talc, especially its characteristic greasy feel, were described by PLINY THE ELDER. The old Arabic word *talq*, which indicates its greasy nature, gave its name to the mineral. In 1550, CATHERINE DE MEDICI made it once again fashionable to use facial makeup in the form of powdered talc colored by the addition of pigments, a fashion that found innumerable imitators and has continued without interruption until today.

1.2. Structure and Mineralogy

Talc, an important industrial mineral, forms with pyrophyllite (Chap. 2) a separate group of silicates within the phyllosilicates, which have a mica-like sheet-silicate structure. Talc is a magnesium hydrosilicate, and pyrophyllite the corresponding aluminum hydrosilicate. The minerals are very similar crystallographically and in their properties.

Pure talc has the chemical composition $3MgO \cdot SiO_2 \cdot H_2O$, corresponding to 63.35 wt % SiO_2, 31.90 wt % MgO, and 4.75 wt % chemically bound water (hydroxide). Its mineralogical chemical formula

$${}^{2}_{\infty}Mg_3^{[6]}\ \{(OH)[Si_2O_5]\}_2 \text{ or}$$

$${}^{2}_{\infty}Mg_3^{[6]}\ [(OH)_2/Si_4O_{10}]$$

clearly represents the layer silicate structure. The talc lattice (see Fig. 1) is composed of infinite two-dimensional (${}^{2}_{\infty}$) silicate double layers ${}^{2}_{\infty}\ \{[Si_2O_5]^{2-}\}_2$ or ${}^{2}_{\infty}\ [Si_4O_{10}]^{4-}$ in which the apical O atoms of all of the SiO_4 tetrahedra within one individual layer point in the same direction, and the OH groups occupy the centers of the hexagons formed by these apical oxygen atoms. The apical O atoms of all of the SiO_4 tetrahedra within an individual layer point in the same direction, and the OH groups occupy the centers of the hexagons formed by these apical oxygen atoms. Within a double layer, the apical O atoms and OH groups of one layer are in direct contact with the corresponding atoms of the other layer, forming octahedral voids. These voids are filled by positively charged magnesium ions, which compensate for the negative charges of the silicate. One magnesium ion is coordinated octahedrally by 4 O and 2 OH, the coordination number being symbolized by $Mg^{[6]}$. The

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a26_047

double layer ("talc layer") so formed is therefore electrically neutral, and is only weakly bonded to the neighboring double layers by Van der Waals forces. This explains the pronounced cleavage properties of talc in the direction {001}.

Structurally, pyrophyllite is comparable to talc, which it also resembles in other respects:

$${}^{2}_{\infty}Al_2^{[6]}\ \{(OH)[Si_2O_5]\}_2 \text{ or}$$

$${}^{2}_{\infty}Al_2^{[6]}\ [(OH)_2/Si_4O_{10}]$$

Unlike talc, the two single layers in pyrophyllite are bonded by Al^{3+} instead of Mg^{2+} ("pyrophyllite layer"). All 3/3 octahedral coordination centers in talc are occupied by $Mg^{[6]}$, but in pyrophyllite only 2/3 are occupied by $Al^{[6]}$. Thus, whereas talc shows trioctahedral cation occupation, in pyrophyllite it is dioctahedral.

The pyrophyllite layer and the talc layer form the basis of the mica structure (→ Mica). In micas, within the pyrophyllite layer (muscovite series) and the talc layer (biotite series), one-fourth of the Si^{4+} ions of the SiO_4 tetrahedra are replaced by Al^{3+}. Charge balance is achieved by the 12-coordinate K^+ ($K^{[12]}$) interspersed between the double layers.

Both minerals form monoclinic crystals with space group $C_{2h}^{6}-C\,2/c$ or $C^{4}_{s}-Cc$. In the most common stacking sequence, $2M_1$, talc has the following lattice constants: $a_0 = 527$ pm, $b_0 = 912$ pm, $c_0 = 1885$ pm, $\beta = 100°\ 00'$.

The axial ratio is $a_0 : b_0 : c_0 = 0.578 : 1 : 2.067$ and $Z = 4$ (number of formula units per unit cell). The interlayer distance $d_{002} = 1/2\,c \cdot \sin\beta$ is 928 pm (9 Å layer silicate). If iron is present, these lattice constants can vary slightly.

The Mg^{2+} in talc can be partly replaced by Fe^{2+} or Ni^{2+}, giving the following talc varieties:

Minnesotaite:

$${}^{2}_{\infty}(Fe^{2+}, Mg, H_2)_3[(OH)_2/(Si, Al, Fe^{3+})_4O_{10}]$$

Willemsite:

$${}^{2}_{\infty}(Ni, Mg)_3[(OH)_2/Si_4O_{10}]$$

Idiomorphic talc formations as crystals, pseudohexagonal lamellae or platelets are rare. The mineral mainly occurs in lamellar or broad columnar, stalked, or spiky aggregates and masses. It commonly occurs in a flaky to compact, dense, tight, microcrystalline form (soapstone or steatite). Talc masses intergrown with chlorite are known as potstone.

Garnierite, $(Ni, Mg)_6[(OH)_8/Si_4O_{10}]$, which was formerly regarded as nickel serpentine or nickel antigorite, is now regarded as a mixture of 7 Å and 10 Å layer silicates, and alternately deposited mineral components. The term garnierite is now restricted to the 9 Å component, which is classed as nickel talc. Together with other nickel hydrosilicates (e.g., with the nickel chlorite schuchardtite), it occurs as an important component of the "New Caledonia" type of deposit, which commercially is a very important type of workable nickel deposit.

1.3. Properties

Talc has a greasy feel due to its very low hardness (Mohs hardness = 1) and cleaves extremely readily parallel to {001}. The density ϱ is 2.7 – 2.8 g/cm^3. The optical refraction (α, β, γ) and birefringence Δ in a thin section under the polarizing microscope are as follows:

$\alpha =$	1.539 – 1.550
$\beta =$	1.589 – 1.594
$\gamma =$	1.589 – 1.596
$\Delta =$	– (0.050 – 0.046)

The optic axial angle is $2V_\alpha = 0 - 30°$ with distinct dispersion $r > v$.

1.4. Occurrence and Origin

Talc is formed under hydrothermal conditions and is a typical mineral of weaker regional metamorphism (regional dynamothermometamorphism). It often occurs in association with chlorite, serpentine, or magnesite.

The main parent rocks that undergo metamorphic mineral reactions leading to talc formation are either (± magnesite-bearing) siliceous dolomites, or olivine- and/or pyroxene-containing ultrabasics. In ultrabasic rocks, talc is often a product of hydrothermal alteration (autometasomatism).

The formation and occurrence of talc can be illustrated by a number of metamorphic mineral reactions that can be reproduced in experimental

hydrothermal syntheses. Increasing temperature shifts the reactions towards liberation of water and CO_2.

$$\underset{\text{Serpentine}}{2\,Mg_3[(OH)_4/Si_2O_5]} + 3\,CO_2 \rightleftharpoons \underset{\text{Talc}}{Mg_3[(OH)_2/Si_4O_{10}]} + \underset{\text{Magnesite}}{3\,MgCO_3} + 3\,H_2O \quad (10)$$

$$\underset{\text{Serpentine}}{5\,Mg_3[(OH)_4/Si_2O_5]} \rightleftharpoons \underset{\text{Forsterite}}{6\,Mg_2[SiO_4]} + \underset{\text{Talc}}{Mg_3[(OH)_2/Si_4O_{10}]} + 9\,H_2O \quad (11)$$

$$\underset{\text{Serpentine}}{Mg_3[(OH)_4/Si_2O_5]} + \underset{\text{Quartz}}{2\,SiO_2} \rightleftharpoons \underset{\text{Talc}}{Mg_3[(OH)_2/Si_4O_{10}]} + H_2O \quad (12)$$

$$\underset{\text{Talc}}{Mg_3[(OH)_2/Si_4O_{10}]} + \underset{\text{Magnesite}}{5\,MgCO_3} \rightleftharpoons \underset{\text{Forsterite}}{4\,Mg_2[SiO_4]} + H_2O + 5\,CO_2 \quad (13)$$

$$\underset{\text{Quartz}}{4\,SiO_2} + \underset{\text{Magnesite}}{3\,MgCO_3} + H_2O \rightleftharpoons \underset{\text{Talc}}{Mg_3[(OH)_2/Si_4O_{10}]} + 3\,CO_2 \quad (14)$$

$$\underset{\text{Talc}}{9\,Mg_3[(OH)_2/Si_4O_{10}]} + \underset{\text{Forsterite}}{4\,Mg_2[SiO_4]} \rightleftharpoons \underset{\text{Anthophyllite}}{5\,(Mg,Fe)_7[(OH)/Si_4O_{11}]_2} + 4\,H_2O \quad (15)$$

$$\underset{\text{Talc}}{7\,Mg_3[(OH)_2/Si_4O_{10}]} \rightleftharpoons \underset{\text{Anthophyllite}}{3\,(Mg,Fe)_7[(OH)/Si_4O_{11}]_2} + \underset{\text{Quartz}}{4\,SiO_2} + 4\,H_2O \quad (16)$$

$$\underset{\text{Talc}}{2\,Mg_3[(OH)_2/Si_4O_{10}]} + \underset{\text{Magnesite}}{MgCO_3} \rightleftharpoons \underset{\text{Anthophyllite}}{(Mg,Fe)_7[(OH)/Si_4O_{11}]_2} + H_2O + CO_2 \quad (17)$$

Assuming that these formulas represent the chemical composition of the parent rock, talc can be formed over a wide temperature range. For example, under isobaric conditions with $X_{CO_2} = 0.3$, the equilibrium temperature for Reaction (1) is 425 °C, while that of Reaction (3) is ca. 50 °C lower (X_{CO_2} is the molar fraction of CO_2 in the gas phase, which consists of CO_2 and H_2O). The upper temperature limit for the existence of talc is set by Reaction (16), which occurs at ca. 700 °C and a water vapor pressure of 1000 bar. Reactions (4) and (7) only occur if magnesite is present with quartz and dolomite in the original rock prior to regional metamor-

phism. Reaction (15) requires the presence of CO_2.

Figure 1. Structure of talc
Projection parallel to c on (001) and a plane perpendicular to the a axis; the monoclinic angle β is 100° 00′
In pyrophyllite, only the locations shown as open circles are occupied by aluminum (2 Al in place of 3 Mg)

In commercially important deposits, talc therefore occurs in association with tremolite, calcite, quartz, and dolomite, as the product of a more intense regional metamorphism of siliceous dolomites, and with forsterite and anthophyllite due to intense regional metamorphic overprint of ultrabasics. However, talc can also be observed as an authigenic new formation, e.g., in sandy sediments and salt deposits.

Reactions (1) – (17) include a number of minerals associated with talc in its deposits. Other minerals that occur in association with talc include chlorites, mica, actinolite, feldspars, rutile, pyrrhotite, pyrite, magnetite, and hematite. Limonite, a product of the weathering of iron-containing minerals, especially iron- containing ore minerals, can often be found interspersed with talc.

1.5. Deposits

Deposits of talc are widely distributed and mined worldwide in regional metamorphic complexes. The important deposits in Europe are:

Germany	Göpfersgrün – Thierstein / Upper Palatinate, Schwarzenbach on the Saale
Finland	Central Finland (Lahnaslampi) near Sotkamo, Polvijärvi and Luikonlahti near Sola), Karelia
France	Pyrenees: Département Ariège (Trimouns near Luzenac)
United Kingdom	Shetland Isles (Baltasound, Unst), Cornwall (Polyphant)
Italy	Fontane / Region Pinerolo, Val Malenco / Region Sondrio, Sardinia (Orani and Nuoro District)
Norway	Nordland (Altermark), Sognefjord (Framfjord), Oppland (Lalm, Sel, Kvam)
Austria	Eastern Styria (Rabenwald, Lassing (closed in 1998) , Weisskirchen, Kleinfeistritz, Oberfeistritz, Stubenberg, Anger)
Sweden	Handöls, Garpenberg
Spain	Provinces of Leon (Puebla de Lillo), Gerona (Pyrenees: Respina), Málaga (Fuengirola), Almeria (Purchena)

Important deposits occur in Canada (Madoc/Ontario and Van Reet/Quebec, which are mined in underground operations, and Penhorwood/Timmins, which is exploited by open-pit mining), the United States [deposits in 11 states; > 80 % of production from Texas: Allamore Talc District with Van Horn/Hudspeth County; also Montana: Yellowstone, Beaverhead, Treasure Chert; Vermont: Hammondville, Rainboro; California (trains carry talc from deposits in the south east to Nevada); New York State], Uruguay, Brazil (Paraná, Sao Paulo; Bahia: Serra das Eguas), Argentina, Australia (Three Springs, Mt. Seabrook/Western Australia; Mt. Fitton/South Australia), Japan (Hokkaido, Kyushu), the People's Republic of China (Haicheng), Taiwan, South Korea (Dongyang/Chungju region, other deposits in the Geangju, Yesan, Muju/Jinan regions), India (Rajasthan, Andhra Pradesh, Madhja Pradesh, Tamil Nadu, Bihar), and the former Soviet Union.

European talc production is ca. 10^6 t/a, of which ca. 450 000 t/a comes from Finland, 280 000 t/a from France, 130 000 t/a from Austria, 80 000 t/a from Spain, 30 000 t/a from Slovakia, and 8500 t/a from Germany.

As talc and pyrophyllite can be substituted for each other in several applications, they are usually grouped together in production and consumption statistics.

Table 1. Comparison of several grades of talc of particle size 98 % < 20 µm (data from manufacturers' information sheets)

Producer	Finnmineral	Luzenac	Norwegian Talc	Naintsch	Cyprus
Type	M 15	20 MO	A.T. 1	ST, micro	Mistron 755
Talc content, wt %	93 – 94	ca. 72	ca. 68	ca. 68	ca. 98

Density, g/cm^3	2.7	2.78	2.9	2.7	2.8

1.6. Processing and Quality Specifications

Depending on the geology and minability of the deposits, talc is extracted either by open-pit mining after removal of the overburden rock layers or by underground mining. Explosives and pick axes are still used in some places, but today mining is mainly carried out mechanically with mobile cutters able to follow the talc body and produce a raw material that is already size reduced.

The processing of talc depends on the type of deposit. Commonly, the first step is selective mining, followed by flotation to separate the talc from other minerals (e.g., silicates and carbonates such as magnesite). Finally, the higher grades of talc are subjected to highly developed beneficiation processes (e.g., fine grinding, air classification).

Many common grades of talc powder are sold without grinding or sieving the mixture of minerals produced by the mine. The talc content then corresponds to the rock composition and is subject to quality variations arising both from the deposit itself and from the method of extraction (contamination with refuse rocks).

Finnish producers use flotation to treat their talc ore, which contains ca. 60 % talc and ca. 40 % associated minerals (mainly magnesite with some dolomite, and, in one deposit, a nickel ore containing ca. 0.2 % Ni). The talc concentrate contains ca. 95 % talc and 3 – 4 % carbonate, the remainder consisting of other mineral impurities.

In the mine, talc or talc-containing mineral mixtures obtained in lump form are crushed with jaw crushers. If necessary, the talc ore is further size reduced with impact or hammer crushers. Grinding is carried out with high-speed impact mills, centrifugal swing-hammer mills, roller mills, tube mills with cylinder charging (cylindrical pebbles), and jet mills.

Under optimum conditions, air classifiers can give a product with 99.7 % < 20 µm and 0.01 % > 45 µm, high-efficiency separators (so-called heavy duty air classifiers) 99 % < 10 µm,

and a jet mill with integrated screen, cyclone, and filter separation up to 98 % < 2 µm.

Grinding of talc first causes delamination of the layers, which requires only small shearing forces. However, fracture normal to the (001) plane (the plane of the layers) requires the usual energy of size reduction. The platelet-like, foliated, lamellar structure is therefore retained in the finely ground powder.

For the production of powdered talc (see Table 1) with a fineness of 98 % < 20 µm and a D_{50} value (the particle size which exceeds that of 50 % of the material and is exceeded by that of the other 50 %) of ca. 3 µm (d_{50} = 3 µm), provided that the talc contains a low level of mineral impurities and has a predominantly lamellar structure, the normal types of grinding equipment require the following amounts of electrical energy (not including the energy required for auxiliary equipment): roller mills ca. 22 kWh/t, impact mills ca. 46 kWh/t, and ball mills ca. 96 kWh/t.

Commonly used are jet mills (air and steam), which require a greater amount of energy. The technical specifications for powdered talc as a filler are laid down in ISO 3262 (see Table 2), which defines talc as "natural, platelet-shaped, lamelliform magnesium silicate hydrate". These standards apply to use in coatings, but can also be used for other areas of application. The four grades, A to D, are essentially defined by the talc content, the loss on ignition, and the content of hydrochloric acid-soluble components (carbonates, chlorites, pyrite and other sulfides, heavy metal oxides, etc.). The particle size, measured by sieve tests, is indicated by appended Arabic numerals (e.g., A1, A2, A3, B1, B2).

Table 2. Quality specifications for type A – D talcs (ISO 3262)

	A	B	C	D
Talc content, %	min. 95	min. 90	min. 70	min. 50
Loss on ingnition	4 – 6.5	4 – 9	4 – 18	4 – 27
HCl-soluble fraction, %	max. 5	max. 10	max. 30	max. 50
Sieve residue, %	1	2	3	
> 45 µm	max. 0.01	0.1	3	
> 63 µm		0.01	0.5	

The following characteristics are typical of pure talc or of talc grades low in accompanying minerals:

- Hydrophobic, organophilic boundary layers parallel to the silicate layers
- Polar and chemosorptive boundary layers (surfaces) at the edges of the platelets and on the fracture surfaces (grinding process), with unsaturated valencies
- A corrosion-inhibiting pH of ca. 8.5
- A platelet-like, lamelliform structure with correspondingly large boundary layer (surface boundary; ratio of the area of the flat surfaces of sheet silicate layers to that of the edges is 200:1)
- Barrier action against diffusion of gases and capillary water
- Morphology-dependent pseudoplasticity
- High electrical surface resistance and bulk resistance
- Low dielectric loss angle
- UV absorption
- Resistance to strong acids and alkalis

The increase in boundary layer (boundary surface) that accompanies increasing fineness of grinding accentuates the typical properties of talc. Mineral impurities lower the quality of talc or talc products, as these impurities do not generally exhibit the properties typical of talc. If the mixture of minerals has a talc content of ≤ 50 %, it is no longer regarded as talc according to DIN and ISO definitions. If the talc mixture contains ≥ 50 % chlorite, it is known as "chlorite, talc-containing" according to DIN 55 629. A product containing < 70 % talc was at one time known as asbestine.

1.7. Uses

The users of talc in the order of consumption volume are the paper industry, ceramics, plastics, paints, roofing and sealants, cosmetics and pharmaceuticals, and agrochemicals, followed by several other smaller consumers.

Some of talc's distinguishing attributes permit its wide use as a filler: smoothness, opacity, porositiy, high sheet retention, low abrasion, low yellow index score.

Paper. In the manufacturing of paper talc is utilized as a filler, for deposit control, and for coating. Paper coatings profit from talc's naturally high brightness, platy structure and its beneficial properties concerning reduced friction,

superior printability, gloss and smoothness. In resin control, the hydrophobic talc particles adhere to the resin and render it harmless. In the paper industry talc has lost some of the market share to cheaper competitors, largely to precipitated and ground calcium carbonate and, to a lesser extent, to kaolin.

Paints and Coatings. Talc is added to paints and coatings in order to produce the following effects:

- Control of the pseudoplasticity (important for processing)
- Ease of redispersion of sediments (important for coatings dispersed in water or other media)
- Improved adhesion to substrates
- Reduced diffusion through coating films (capillary water, gases)
- Synergy with inhibitor pigments (anticorrosion)
- Improved light scattering (especially in emulsion paints)
- Resistance to weathering and atmospheric influences
- Resistance to acids and alkalis
- Good dielectric properties

By combining platelet-like, flaky talc with needle-like silicates, such as amphiboles, wollastonite, xonotlite, sillimanite, and sintered mullite, interesting effects with regard to thixotrophy, close packing of particles, and elastic strengthening of the matrix can be produced.

The most important uses for talc as a filler in paints and coatings are in:

- Primer paints (based on polyvinyl butyral resin)
- Anticorrosion primer paints
- Undercoats and intermediate fillers
- Coil coatings and powder coatings
- Coatings for plastics
- Emulsion paints (especially one-coat paints), synthetic plasters, and fillers
- Epoxide – tar and polyurethane – tar coatings
- Bitumen coatings

Talc is used as a filler in a wide range of paints for domestic, industrial and protective coatings, because its particles reinforce paint, reduce sagging and give rise to a flattened coat and a smooth film. The amount of talc in paints ranges up to 30 wt %. Talc is the most common extender mineral in heavy duty applications (e.g., marine and protective coatings).

Plastics. Thermoplastics strengthened by the addition of talc to give improved tensile and transverse strength, modulus of elasticity, refractory properties, and dimensional stability are widely used as construction materials. The addition of talc has a very favorable effect on the mechanical properties and hence the serviceability of polypropylene and polyurethane (see Figs. 2 and 3).

Figure 2. Mechanical properties of polypropylene reinforced with talc
a) With talc type A1 (98 % talc < 10 µm); b) With talc type C1 (68 % talc < 10 µm)

As a filler in polypropylene it improves surface properties (e.g., scratch resistance). The filler content can be up to 40 %. In the automotive industry polypropylene is used for dashboards, interior trim, bumpers, etc. Talc is also used to produce engineering thermoplastic resins (e.g., nylon compounds to replace aluminum parts in inlet manifolds).

Figure 3. Mechanical properties of elastic polyurethane reinforced with talc
a) With talc type A1 (98 % talc < 10 µm); b) With talc type C1 (68 % talc < 10 µm)

Ceramics. Talc is used in traditional ceramics (e.g., 30 – 60 % in tiles, hobbyware bodies) and in technical ceramics (e.g., main silicate mineral instead of clays and feldspar in lower grade alumina products: steatite and low-expansion cordierite ceramics). In traditional ceramics, the bodies are fired for over 12 h below 1179 °C (below cone 2), and the porous bodies are then glazed and refired. For this application the talc should contain tremolite and carbonate because these minerals provide for enhanced pressing and permeability characteristics. Otherwise wollastonite must be added to purer talc to improve these properties.

Talc in the massive form known as steatite can be processed and formed directly by cutting and sawing, and in block form it can be used for thermal insulating and electroceramic products. Here, the important properties of talc are its low hardness (enabling it to be easily cut and shaped), the stability of cut products towards firing, and the very low degree of shrinkage, which means that the shaped raw material can be fired directly to porcelain.

Steatite ceramics are used in electrical insulating applications (see → Insulation, Electric, Chap. 3.1.2.2.). Steatite must be extremely pure to obtain consistency and to exclude shrinkage. For producing these low-loss bodies, ca. 10 % kaolin and 10 % barium carbonate are added to this type of talc, which is fired at 1349 – 1355 °C (cone 12 – 13).

Cordierite ceramic bodies can be produced from a mixture containing pure talc (44 %), kaolin (41 %) and alumina (15 %) or from a 1:1 mixture of kaolin and chlorite (chloritic talc). The manufacturing of these ceramics, utilized for automotive catalyst supports, is more expensive because of the higher firing temperatures.

Other Uses. For many other uses, talc is first ground. Powdered talc is used as a lubricant or polishing agent, in pastels, as a filler in the pigment industry, in cosmetics (face powder), as an additive for soaps, in paper production, as a finishing agent in the textile industry, as a filler and glazing agent in a wide range of industries, as a filler in the plastics and rubber industries, as coating for rubber products to avoid sticking and in asphalt processing.

Talc is used as an *antiblocking agent* for plastic films, for example to facilitate the opening of plastic bags such as those used for fruits and vegetables in supermarkets. For these applications a pure white talc, which is used in amounts of up to 2 kg/t, with an ultrafine size of 4 µm, is required to maintain the film color and transparency. Here talc is in competition with two cheaper rivals, namely, diatomaceous earth and synthetic silica. Sophisticated processing is required to obtain ultrafine (< 10 µm) grades of talc, and only a few producers are able to supply these.

A limited amount of talc (< 2 % of world mine production) is utilized in the *cosmetic industry*, mostly for body talcs (its pH and surface area permit it to act as a perfume carrier) but also as a filler in solid antiperspirant sticks, giving good skin slip, and in color cosmetics. Talc provides cosmetics with stability, texture, skin adhesion, slip, and water resistance. Micronized material with a grain size of < 5 µm is used in compressed products to prevent trapped air from

impairing the quality. In some applications talc is treated with hydrophobic coatings.

The amount of pure high-value talc which is consumed by the *pharmaceutical industry* is very limited. Furthermore, this talc quality requires sophisticated processing to remove all impurities (e.g., accessory minerals, carbon, iron oxide, base metal traces) and special treatments (e.g., cleaning with dilute hydrochloric acid, washing, drying, sterilization by heating to 160 °C or exposure to gamma radiation or ethylene oxide). The main applications of talc are dusting (90 – 99 % talc) and in tablets (1 – 10 % talc as a glidant or lubricant, 5 – 30 % talc as a diluent). Talc must not be used to dust surgical gloves because it can contaminate wounds.

In *agriculture*, talc satisfies all criteria (inertness, compatibility with the active ingredient, fineness, and low abrasiveness to equipment) required of a dry carrier for pesticides, fertilizers, herbicides, fungicides, and insecticides. It is used in granules and wettable powders but not in liquid formulations. In these applications, talc competes with other materials, such as fuller's earth, kaolin, diatomite, perlite, gypsum and sepiolite. The largest consumer of talc (commonly of low grade with 95 % < 325 mesh) is for pesticides.

In *animal feeds*, talc is used as an anticaking coating in feed bins and as a coating on the feed itself. Since talc is nontoxic, it is harmless and poses no danger to livestock. Its hydrophobicity prevents water loss and absorption. Furthermore, it protects the products and enables free flowing through the production and packaging plant. The amount of talc in animal feed is up to 1 – 2 % in meal and up to 0.3 – 0.5 % in pellets.

Roofing applications exploit talc (commonly < 80 mesh, passing 180 µm) as a stabilizer for the asphalt of tar paper, asphalt shingles, and roll roofing; it improves weathering and fire resistance.

A mixture of talc and chlorite with a specific size distribution, developed by Talc de Luzenac, improves the separation of waste from the water in biological *wastewater treatment* plants.

In the *rubber industry*, talc in fine grades and free of impurities is utilized mostly to lubricate molds, to prevent surfaces from sticking together, and as a mold release agent since it maintains its lubricating properties at high temperatures. As a rubber filler, talc is in carpet backing, valves, and cable insulation but is not suitable for tire manufacturing because of its low hardness and platy cleavage.

Some *minor applications* of talc are the sealant industry (e.g., joint compounds, dry wall compounds, butyl caulks, polyurethane sealants), sculpturing (e.g., steatite and soapstone for producing decorative articles), food (e.g., preparation, mostly polishing, of foodstoffs including cereals and rice, coating of chewing gum to avoid sheets sticking together) and polishing (when good color and limited abrasion is required, such as shoe, floor, and car polishing).

1.8. Economic Aspects

Worldwide, the output and consumption of talc, including pyrophyllite, exceeds 8×10^6 t/a, of which pyrophyllite accounts for ca. 2×10^6 t/a, i.e., about 25 %. In Western Europe, pyrophyllite is of minor economic importance; production and consumption of talc amount to ca. 10^6 t/a. Germany has to import most of its talc requirements. The main applications for talc in Western Europe are for paints and pigments, followed by paper, cosmetics, pharmaceuticals and rubber. The approximate percentage market shares of the major talc applications in Western Europe were:

Paper and pulp	52
Paints and varnishes	11
Roofing	7
Ceramics	6
Polymers	7
Plastics	5
Animal feedstuff	5
Fertilizers	3
Pharmaceuticals and cosmetics	3
Others	6

In Europe, the talc industry and talc production is concentrated in the hands of four companies (Talcs de Luzenac of France, Western Mining Corporation of Austria, Plüss-Staufer of Switzerland, and IMI Fabi of Italy). Finnminerals Oy of Finland, a large producer of talc, is now owned jointly by Plüss-Staufer and Western Mining Corporation.

1.9. Toxicology

Pure talc is toxicologically harmless. However, where there are high concentrations of dust in the air, face masks should be worn. If the talc contains detectable amounts of asbestos or asbestos minerals, an MAK value of 2.0 mg/m^3 applies. Talc is a nontoxic, inert substance or raw material, but it can contaminate wounds and if inhaled it can cause lung irritations.

2. Pyrophyllite

2.1. Introduction

The important industrial mineral pyrophyllite forms, with talc, a special group of phyllosilicates (layer silicates) with mica-like sheet silicate structures. Pyrophyllite is an aluminum hydrosilicate, whereas talc is the corresponding magnesium hydrosilicate. Pyrophyllite is similar to talc crystallographically and even more so in its other properties.

2.2. Structure and Mineralogy

The pyrophyllite structure (see Fig. 4) contains an infinite coherent two-dimensional silicate double layer of linked $[SiO_4]$ tetrahedra: ${}^2_\infty\{[Si_2O_5]^{2-}\}_2$ or ${}^2_\infty[Si_4O_{10}]^{4-}$, in which all apical O atoms of the SiO_4 tetrahedra within one $[SiO_5]$ layer point in the same direction, and the OH groups occupy the centers of the hexagons formed by these oxygen atoms. In the double layer, the oxygen layers formed by the O atoms and OH groups are situated directly opposite each other, and they are linked together by Al^{3+}, which is octahedrally coordinated by 4 O and 2 OH. This coordination number is symbolized by $Al^{[6]}$. The resulting silicate double layer ("pyrophyllite layer") is therefore electrically neutral and is only weakly bonded to the neighboring double layers by Van der Waals forces. This results in the laminar structure and pronounced cleavage of pyrophyllite in the direction (001). In talc, unlike pyrophyllite, the two single layers are bonded by Mg^{2+} ("talc layer") instead of Al^{3+}. Thus, in pyrophyllite only 2/3 of the octahedral coordination centers are occupied by $Al^{[6]}$, while all 3/3 in talc are occupied by $Mg^{[6]}$. Whereas pyrophyllite shows dioctahedral cation occupation, in talc it is trioctahedral, similar to the corresponding charged mica layers, e.g., in muscovite

$$K^+\{Al_2[(OH)_2/Si_3AlO_{10}]\}^-$$

Figure 4. Structure of pyrophyllite
Projection parallel to c on (001) and a plane perpendicular to the a axis; the monoclinic angle β is 99° 55′

Pure pyrophyllite has the chemical composition $Al_2O_3 \cdot 4\,SiO_2 \cdot H_2O$, corresponding to 66.7 wt % SiO_2, 28.3 wt % Al_2O_3, and 5.0 wt % chemically bound water (hydroxide). Its mineralogical chemical formula is

$${}^2_\infty Al_2^{[6]}\{(OH)[Si_2O_5]\}_2 \text{ or}$$

$${}^2_\infty Al_2^{[6]}[(OH)_2/Si_4O_{10}]$$

Pyrophyllite forms monoclinic crystals with space group $C^6_{2h} - C\,2/c$ or $C^4{}_s - Cc$ and has the following lattice constants: $a_o = 515$ pm, $b_o = 892$ pm, $c_o = 1859$ pm, $\beta = 99°\ 55'$.

The axial ratio is $a_o : b_o : c_o = 0.577 : 1 : 2.084$ and $Z = 4$ (number of formula units per unit cell). The interlayer distance $d_{002} = 1/2\,c \cdot \sin\beta$ is 916 pm. If iron is present, these lattice constants can vary slightly.

The Al^{3+} in pyrophyllite can be partly replaced by ca. 2 atom % (average) of Fe^{3+}. The small amounts of MgO and CaO found in many

analyses can be attributed to mechanical contamination of the analytical samples. Chrome pyrophyllite, containing ca. 3 wt % Cr_2O_3, also occurs naturally.

2.3. Properties

Pseudohexagonal lamellar or tabular crystals, developed in the {001} direction, are always formed in coarse radial, random, or fan-shaped crystalline aggregates. Massive pyrophyllite is known as agalmatolite or figure stone (e.g., large deposits in Minas Gerais/Brazil). Pyrophyllite is translucent, silvery or silvery-white, white, yellowish, golden yellow, greenish, or apple green and has a nacreous luster. The lamellae are flexible and have a slightly greasy feel. Cleavage in the (001) plane is fully developed. The Mohs hardness is 11/2 and the density 2.79 g/cm^3.

Since water in pyrophyllite is in the form of hydroxide only, strong heating is needed to evolve it, leading to exfoliation and the formation of wormlike shapes. Pyrophyllite is difficult to melt. It is only slowly decomposed by sulfuric acid, but is more readily attacked by hydrofluoric acid.

In thin sections under the polarizing microscope, pyrophyllite is always colorless ($x<y\approx z$). Its optical refraction α, β, γ and birefringence Δ are

$\alpha =$	1.552 – 1.556
$\beta =$	1.558 – 1.589
$\gamma =$	1.600 – 1.601
$\Delta =$	– (0.048 – 0.045)

The optic axial angle is $2\,V_\alpha = 53-62°$ with weak dispersion $r > v$.

Depending on its origin, pyrophyllite can mainly consist either of soft, fragile aggregates or coarsely radiating lamellar crystals, very similar to lamellar talc, or of dense, coarse aggregates with an uneven, matt to lustrous fracture, similar to massive talc.

2.4. Formation

Pyrophyllite can occur in pneumatolytic formations, where it is formed by the transformation of aluminum-rich silicates (e.g., vein deposits with cassiterite or amblygonite). In hydrothermal regions, pyrophyllite can be formed from feldspar if the alkali metals can be removed by hydrothermal solutions, or from kyanite (disthene), andalusite, kaolinite, etc., provided that there is a supply of SiO_2. Suitable rocks (such as tuffs and acidic extrusive rocks, e.g., hyalorhyolite) can be (hydrothermally) altered, sometimes completely, into pyrophyllite rock or agalmatolite. The transport of pyrophyllite in hydrothermal solutions leads to its deposition in fissures, where it occurs with quartz. Pyrophyllite also occurs with quartz in nodules and lenses of regional metamorphic rocks (crystalline schists). In regional metamorphic formations, pyrophyllite can be found in the weak epizones.

Important metamorphic mineral reactions which elucidate the occurrence and distribution of pyrophyllite in certain formations include

$$\underset{\text{Lawsonite}}{CaAl_2[(OH)_2/Si_2O_7]\cdot H_2O} + \underset{\text{Quartz}}{2SiO_2} + CO_2 \rightleftharpoons \underset{\text{Calcite}}{CaCO_3} + \underset{\text{Pyrophyllite}}{Al_2[(OH)_2/Si_4O_{10}]} + H_2O$$

$$\underset{\text{Kaolinite}}{Al_4[(OH)_8/Si_4O_{10}]} + \underset{\text{Quartz}}{4SiO_2} \rightleftharpoons \underset{\text{Pyrophyllite}}{Al_2[(OH)_2/Si_4O_{10}]} + H_2O$$

The equilibrium conditions of this metamorphic reaction are (with $P_{H_2O} = P_{total}$):

1000 bar/325 ± 20 °C;
2000 bar/345 ± 10 °C;
4000 bar/375 ± 15 °C.

$$\underset{\text{Pyrophyllite}}{Al_2[(OH)_2/Si_4O_{10}]} + \underset{\text{Calcite}}{CaCO_3} \rightleftharpoons \underset{\text{Margarite}}{CaAl_2[(OH)_2/Al_2Si_2O_{10}]} + \underset{\text{Quartz}}{6SiO_2} + H_2O + CO_2$$

$$\underset{\text{Margarite}}{CaAl_2[(OH)_2/Al_2Si_2O_{10}]} + \underset{\text{Quartz}}{4SiO_2} \rightleftharpoons \underset{\text{Anorthite}}{Ca[Al_2Si_2O_8]} + \underset{\text{Pyrophyllite}}{Al_2[(OH)_2/Si_4O_{10}]}$$

$$\underset{\text{Pyrophyllite}}{2Al_2[(OH)_2/Si_4O_{10}]} + \underset{\text{Fe-rich Chlorite}}{\{Fe_2Al(OH)_6\}\cdot\{Fe_2Al[(OH)_2/Al_2Si_2O_{10}]\}} \rightleftharpoons \underset{\text{Chloritoid}}{2Fe_2AlAl_3[(OH)_4/O_2/(SiO_4)_2]} + \underset{\text{Quartz}}{6SiO_2} + 2H_2O$$

$$\underset{\text{Pyrophyllite}}{Al_2[(OH)_2/Si_4O_{10}]} \rightleftharpoons \underset{\text{Andalusite, Kyanite}}{AlAl[O/SiO_4]} + \underset{\text{Quartz}}{3SiO_2} + H_2O$$

Under certain hydrothermal conditions, pyrophyllite can be converted into diaspore (α-AlOOH).

Pyrophyllite can be synthesized from neutral or strongly acid colloidal solutions of aluminum hydroxide and SiO_2 at high temperatures (420 – 575 °C) and relatively low pressures.

2.5. Deposits

Economically important deposits are located in Hirvivaara (northern Finland), on Fukue Island off Nagasaki (Japan), and in South Korea, the United States, Canada, Brazil, Thailand, India, South Africa, Argentina, and Peru. Pyrophyllite is mainly open-pit mined. World production amounts to ca. 25 % of the total production of talc/pyrophyllite. Talc and pyrophyllite have some similar properties and are therefore grouped together in some production and consumption statistics.

Table 3. Chemical composition (in wt %), hardness, and refractive index of two grades of processed Australian pyrophyllite

	Grade 1	Grade 2
SiO_2	65.8	67.5
Al_2O_3	28.2	25.5
FeO	0.01	0.07
Fe_2O_3	0.11	0.29
TiO_2	0.18	0.18
MgO	0.01	0.03
CaO	0.28	0.26
Na_2O	0.10	0.12
K_2O	0.04	0.55
CO_2	0.05	0.10
SO_3	0.04	0.11
H_2O (chemically bound)	4.95	4.75
Hardness (Mohs)	$1-1\frac{1}{2}$	$1-1\frac{1}{2}$
Refractive index	1.58	1.58

By far the most important reserves are the Roseki deposits (“ wax stone”, the Japanese term for hydrothermally formed pyrophyllite-rich rocks with a waxy appearance) in Japan (Mitsuishi District/Okayama Prefecture, Shokozan District/Hiroshima Prefecture SW of Honshu, Goto District/Nagasaki Prefecture on Goto Island) and the Nab-Suk deposits (Korean term for deposits of similar origin to the Japanese “Roseki”) in South Korea (southeast: Wondong, Milyang, Dongnae, and in the far southwest: Wando, Kasado, Sungsan). Other deposits are found in northern Finland (Hirvivaara), in the United States (North Carolina: Robbins, Glendon, Hillsborough, and also California), in Canada (Manuels/Newfoundland), Brazil (Districts of Onca de Pitangui and Matheus Leme in Minas Gerais), India (Madhya Pradesh, Uttar Pradesh), Thailand, Turkey (Malatya Province), and Australia (Pambyula/New South Wales). In the Republic of South Africa (Ottosdal/Lichtenburg District) “ wonderstone” is extracted, which contains 90 % pyrophyllite with some epidote, chlorite, and rutile.

2.6. Processing, Quality Requirements, and Uses

Processing is similar to that for talc (see Section 1.6). As pyrophyllite has very similar properties to talc (see Table 3), its industrial uses are also similar, and the minerals can be substituted for one another. However, as pyrophyllite differs from talc of similar purity in some of its characteristic properties, it is seldom processed to a quality corresponding to Type A1 talc. Outside Europe (e.g., Japan, South Korea, United States), pyrophyllite is also used as a raw material in the refractory industry. A special application is in diamond synthesis where it is used as a lining material for the ultrahigh pressure cells. In this application it is advantageous that the melting point of pyrophyllite increases with increasing pressure.

The percentage of pyrophyllite consumed for industrial ceramics is considerably greater than that of talc.

In its use as a filler and in its properties important for this and other uses, pyrophyllite is very similar to talc. Pyrophyllite is used as a filler in coatings, plastics, adhesives, and other industrial chemical products, mainly in eastern Asia, where, in contrast to Europe and the United States, it can be produced and purchased more cheaply.

3. Chlorite

The chlorites (“14 Å chlorites”) form a very heterogeneous group and can sometimes be important rock-forming minerals. Their chemical structure (Fig. 5) shows them to be essentially hydrated Mg – Fe – Al silicates that are free of

alkali metals and calcium and are built up of two kinds of oppositely charged layer ions.

Figure 5. Idealized structure of chlorite
Projection on a plane perpendicular to the *a* axis

Formerly, low-iron orthochlorites were regarded as "true chlorites" and were distinguished from iron-rich leptochlorites. However, orthochlorites are now considered to be those in which $Fe_2O_3 < 4\,\%$, and leptochlorites those in which $Fe_2O_3 > 4\,\%$.

In the chlorites, trioctahedral phyllosilicates (layer silicates) are present, consisting of negatively charged mica layers (→ Mica; → Silicates, Chap. 1.1., → Silicates, → Silicates) alternating with positively charged brucite-like layers. All octahedral sites are occupied by cations (Mg, Al, Fe) forming trioctahedral layer silicates.

As in the other phyllosilicates, the Si^{4+} in chlorites is partly replaced by Al^{3+} in the tetrahedral positions of the mica layer. Charge balance is achieved by the replacement of divalent cations (Mg^{2+}, Fe^{2+}, Mn^{2+}, Cr^{2+}, Ni^{2+}) by trivalent cations (Al^{3+}, Fe^{3+}) in the hydroxide layer. This results in a large number of possible chemical variants, and further variations can result from the replacement of Mg^{2+}, mainly by Fe^{2+}, in the octahedral positions of both the talc layer and the brucite layer.

In contrast, the sudoite series of minerals, which have only been known since the early 1960s, are "dioctahedral chlorites". They consist of alternating muscovite and (charged) brucite layers. Charge compensation, necessary because of the partial substitution of Si by Al in the $[SiO_4]$ tetrahedra, results from the introduction of trivalent in place of divalent cations in the brucite-like layer as well as by over-occupation of the octahedral interstices.

With regard to the six octahedrally coordinated cations, the minerals of the chlorite series can also be regarded as mixed crystals of four end members, although these are hypothetical, and do not occur in nature in the pure state:

Fe_6 Chlorite $\left\{\begin{array}{l} Fe_3^{2+}[(OH)_2/Si_3AlO_{10}]^- \\ Fe_2^{2+}Fe^{3+}(OH)_6^+ \end{array}\right\}$

Mg_5Al Chlorite $\left\{\begin{array}{l} Mg_3[(OH)_2/Si_3AlO_{10}]^- \\ Mg_2Al(OH)_6^+ \end{array}\right\}$
chemical composition comparable to antigorite

$Fe_4^{2+}Al_2$ Chlorite $\left\{\begin{array}{l} Fe_2^{2+}Al[(OH)_2/Al_2Si_2O_{10}]^- \\ Fe_2^{2+}Al(OH)_6^+ \end{array}\right\}$
daphnite

Mg_4Al_2 Chlorite $\left\{\begin{array}{l} Mg_2Al[(OH)_2/Al_2Si_2O_{10}]^- \\ Mg_2Al(OH)_6^+ \end{array}\right\}$
chemical composition comparable to amesite

However, the two magnesium-rich minerals antigorite and amesite, sometimes described as end members, do belong to the serpentine minerals and not to the chlorites. The conversion from the chlorite structure to the serpentine structure only requires the apical O atoms of half of the T_2O_5 (T = Si, Al) layers to be shifted to the other side. If the transformation is only partial, the poorly crystallized 7 Å chlorites or septechlorites result.

The minerals of the chlorite series form monoclinic crystals, usually with the space group $C_{2h}{}^3 - C\,2/m$, $Z = 4$ (number of formula units per unit cell). However, the number of possible stacking variations is much greater than in the case of micas.

Much simplified, chlorite has the following lattice constants: $a_o \approx 530$ pm (5.3 Å), $b_o \approx 930$ pm (9.3 Å), $c_o \approx 2860$ pm (28.6 Å). The axial ratio is $a : b : c \approx 0.57 : 1 : 3.09$, $\beta \approx 97°$. The layer thickness is $d_{002} = 1420$ pm (14 Å layer silicate).

Of the trioctahedral chlorites (chlorites in the narrower sense), several groups ("series") can be distinguished.

The talc chlorites include:

Talcchlorite (hypothetical end member) $\left\{\begin{matrix} Mg_3[(OH)_2/Si_4O_{10}] \\ Mg_3(OH)_6 \end{matrix}\right\}$ (same chemical composition as serpentine, $Mg_3[Si_2O_5/(OH)_4]$, which is thermodynamically more stable)

Penninite $\left\{\begin{matrix} (Mg, Al)_3[(OH)_2/Al_{0.5-0.9}Si_{3.5-3.1}O_{10}] \\ (Mg, Al)_3(OH)_6 \end{matrix}\right\}$

Clinochlore $\left\{\begin{matrix} (Mg, Al)_3[(OH)_2/AlSi_3O_{10}] \\ (Mg, Al)_3(OH)_6 \end{matrix}\right\}$

Sheridanite $\left\{\begin{matrix} (Mg, Al)_3[(OH)_2/Al_{1.2-1.5}Si_{2.8-2.5}O_{10}] \\ (Mg, Al)_3(OH)_6 \end{matrix}\right\}$

Rhipidolite $\left\{\begin{matrix} (Mg, Fe, Al)_3[(OH)_2/Al_{1.2-1.5}Si_{2.8-2.5}O_{10}] \\ (Mg, Al)_3(OH)_6 \end{matrix}\right\}$

Corundophilite $\left\{\begin{matrix} (Mg, Fe, Al)_3[(OH)_2/Al_{1.5-2}Si_{2.5-2}O_{10}] \\ (Mg, Al)_3(OH)_6 \end{matrix}\right\}$

The ferro chlorites are formed from

Brunsvigite $\left\{\begin{matrix} (Fe^{2+}, Mg, Al)_3[(OH)_2/AlSi_3O_{10}] \\ (Fe, Mg, Al)_3(OH)_6 \end{matrix}\right\}$

Daphnite $\left\{\begin{matrix} (Fe^{2+}, Al)_3[(OH)_2/Al_{1.2-1.5}Si_{2.8-2.5}O_{10}] \\ (Fe, Al)_3(OH)_6 \end{matrix}\right\}$

Pseudo-thuringite $\left\{\begin{matrix} (Fe^{2+}, Al, Mg)_3[(OH)_2/Al_{1.5-2}Si_{2.5-2}O_{10}] \\ (Fe, Mg, Al)_3(OH)_6 \end{matrix}\right\}$

The ferro-ferri chlorites include the following: (oxychlorites with partial dehydrogenation: $Fe^{2+} + OH^- \longrightarrow Fe^{3+} + O^{2-} + 1/2\,H_2$)

De-lessite $\left\{\begin{matrix} (Mg, Fe^{2+}, Fe^{3+})_3[(O, OH)_2/Al_{0-0.9}Si_{4-3.1}O_{10}] \\ (Mg, Fe^{2+})_3(OH)_6 \end{matrix}\right\}$

Chamosite $\left\{\begin{matrix} (Fe^{2+}, Fe^{3+})_3[(O, OH)_2/AlSi_3O_{10}] \\ (Fe, Mg)_3(OH)_6 \end{matrix}\right\}$

Thu-ringite $\left\{\begin{matrix} (Fe^{2+}, Fe^{3+}, Al)_3[(O, OH)_2/Al_{1.2-2}Si_{2.8-2}O_{10}] \\ (Mg, Fe, Fe^{3+})_3(OH)_6 \end{matrix}\right\}$

The following can also be mentioned here:

Pennantite $\left\{\begin{matrix} (Mn, Al, Fe^{3+})_3[(OH)_2/(Al, Si)Si_3O_{10}] \\ (Mn, Al)_3(OH)_6 \end{matrix}\right\}$

Gonyerite $\left\{\begin{matrix} (Mn, Mg, Fe^{3+})_3[(OH)_2/(Si, Fe^{3+})Si_3O_{10}] \\ (Mn, Mg, Fe^{3+})_3(O, OH)_6 \end{matrix}\right\}$

Chromium chlorites include:

Kämmererite $\left\{\begin{matrix} (Mg, Cr)_{<3}[(OH)_2/AlSi_3O_{10}] \\ (Mg, Cr)_3(OH)_6 \end{matrix}\right\}$

Kochubeite $\left\{\begin{matrix} (Mg, Al)_{<3}[(OH)_2/(Cr, Al)Si_3O_{10}] \\ (Mg, Al)_3(OH)_6 \end{matrix}\right\}$

Nickel chlorites also occur: schuchardtite is a nickel penninite which contains less nickel than magnesium, whereas in nimite, nickel predominates.

Crystals of chlorite are only occasionally found, and are usually lamellar and in flake or massive form. Well-developed crystals usually have a hexagonal, rhombohedral, or pseudohexagonal tabular crystal habit.

The Mohs hardness is ca. 2, and the density (depending on iron content) ca. 2.6 – 3.3 g/cm^3. Unlike the micas, lamellae of chlorite are not elastically flexible.

Owing to the lamellar twinning commonly present, the crystals appear optically uniaxial. There are several twinning "laws", e.g., the penninite law [twinning plane (001)] or the mica law (twinning plane perpendicular to (001) and parallel to [110]). Also, twinning occurs even in the lattice, leading to polytypes, which have different symmetries and multiple c values (variations in stacking sequence).

Depending on chemical composition, the optical character of the chlorites is either biaxially positive or biaxially negative, and is sometimes different for different wavelengths. The plane of the optical axis is usually (010), and the acute bisectrix is approximately normal to (001).

Chlorites usually have a green color, from which the name is derived. As the iron content increases, the color becomes more intense, increasing from colorless to dark green or brownish green (on oxidation of the iron). Other colors include pink to violet-pink (chromium chlorites) and orange-red (higher Mn content and lower Fe content).

The optic axial angle can vary greatly ($-20°$ to $+70°$), e.g., for clinochlore and grochauite (iron-containing sheridanite) $2V_\gamma = 0 - 70°$, and for daphnite, bavalite, and thuringite $2V_\alpha = 0 - 30°$. However, optic axial angles are usually very small, converging to 0°.

The iron content has a considerable influence on optical refraction. Increasing iron content leads to an increase in optical refraction (α,

β, γ), while the birefringence Δ is usually low. Pleochroism is usually strongly developed.

Mg chlorites:		Penninite	Clinochlore	Sheridanite
	α =	1.562	1.581	1.594
	β =	1.565	1.581	1.594
	γ =	1.565	1.586	1.606

Anomalous interference colors can often occur. Optically positive chlorites with low iron content and low refractive index show typical anomalous brown (“ leather brown”) interference colors, whereas optically negative chlorites with higher iron content and higher refractive index show anomalous violet to blue (“ duck blue” or “ mallard blue”) interference colors.

If chlorites are heated, they liberate water in two steps, but their structure remains unchanged almost up to complete dehydration. With magnesium-rich chlorites, water is first liberated from the brucite layers, and olivine is formed in the second dehydration step. Further temperature increase leads to the formation of spinel and enstatite.

As a rock-forming mineral, chlorite occurs mainly in low-grade regional metamorphic rocks or epizonal crystalline schists, i.e., in the metamorphites of the greenschist facies (e.g., chlorite schists). Low-iron chlorite often occurs in association with talc. Also, chlorite is widely distributed as a hydrothermal druse mineral. Chlorite is often formed by hydrothermal decomposition and alteration (“chloritization”) of various (magnesium-rich) silicates, e.g., from biotite, garnet, hornblende, and augite; it also displaces and causes pseudomorphism of these minerals. Chlorites are also formed by the transformation of ultrabasic rocks (mainly olivine-rich rocks) into serpentinites (serpentinization). Chlorite can also be formed by contact metamorphism (e.g., of rocks of the albite – epidote – hornfels facies). Clay sediments often contain chlorite, usually of diagenetic origin.

The iron-rich chlorites, e.g., chamosite (in the Jura mountains from Chamoson in Wallis/Switzerland) and thuringite (Thuringia/Federal Republic of Germany), which practically correspond to the older leptochlorites, can occur in certain oolitic iron deposits, and can even be the predominant mineral in some places. These formations are due to sedimentary deposition, but now exist in a slightly metamorphosed form.

The nickel chlorite schuchardtite occurs near other nickel hydrosilicates (e.g., with garnierite, hitherto classified as nickel serpentine or nickel antigorite, with the mineralogical chemical formula $(Ni, Mg)_6[(OH)_8/Si_4O_{10}]$, more recently also regarded as mixtures, so that garnierite is then restricted to the 10 Å component as nickel talc) in the “New Caledonia” type nickel deposits, which are of major economic importance.

The chromium chlorites, which are characterized by their pink to peach-blossom or violet-pink colors, occur in chromite deposits. They were formed by the serpentinization of the chromite- containing ultrabasic parent rocks.

Apart from its use as an ore [an important iron ore in former times, and a nickel ore today (→ Nickel)], chlorite is at present only of minor importance as an industrial mineral (e.g., as a filler, pigment, or pigment matrix) in spite of its wide distribution and frequent occurrence in lamellar form. Its potential as a replacement for other minerals (e.g., talc, mica), which have

some similar properties is somewhat limited at present. Chlorite (penninite) is sometimes used in the wallpaper industry. Leuchtenbergite, an almost iron-free variety of clinochlore, together with sericite and quartz, is the most important component of "white schist", a metamorphic rock of which there are deposits, for example, at Aspang (Ausschlag-Zöbern in Lower Austria). Although white schist is known as "Aspang kaolin", it contains no kaolin and is mainly of interest for its sericite content.

Chlorite and talc have similar properties. Thus, chlorite can substitute talc, e.g., in some ceramic applications. Chlorite is often found in talc deposits.

More recently, amixture of talc and chlorite with a specific size distribution, developed by Talc de Lucerne, improves the separation of waste material from the process water, and is used in biological wastewater treatment where it is added to the biological pool.

1. Introduction

"Tall" is the Swedish word for pine, and the term tall oil is an American adaptation of "tallolja," a Swedish product name associated with the kraft pulping process (→ Paper and Pulp, Chap. 1.3.1.1.) and with products from the fractional distillation of crude tall oil.

Pine wood contains an extractable fraction, ≈ 3 %, consisting of free and combined fatty and rosin acids and nonacidic compounds (tall oil components). In the alkaline pulping process the tall oil components are saponified into a soapy material that, when acidulated, gives a mixture of free rosin and fatty acids and neutral components – crude tall oil. Crude tall oil is refined mainly by vacuum distillation processes to separate the various compounds almost completely into rosin and fatty acid fractions.

The *rosin* part of crude tall oil is a complex mixture of rosin acids, a three-ring fused system with the empirical formula $C_{20}H_{30}O_2$ (→ Resins, Natural, Chap. 5.2.3., → Resins, Natural, Chap. 5.4.). The tall oil *fatty acids*, primarily C_{18} types, are similar in composition to those derived from soybean oil. The *neutral constituents* of tall oil – predominantly esters, sterols, and hydrocarbons – are generally regarded as troublesome "impurities" that impair its utilization and distillation.

Abbreviations of basic tall oil names and common analyses are often used in publications and reports.

Crude tall oil (CTO) [*8002-26-4*]
Tall oil fatty acids (TOFA) [*61790-12-3*]
Tall oil rosin (TOR) [*8052-10-6*]
Distilled tall oil (DTO) [*8002-26-4*]
Tall oil pitch (TOP) [*8016-81-7*]
Heads, light ends (H) [*65997-03-7*]

2. Crude Tall Oil as Byproduct and Raw Material

The kraft pulping process was developed late in the 19th century. Some years later it was discovered in Sweden that a product similar to oil or wood tar could be obtained when the soapy material was acidulated with sulfuric acid. The recovery of byproducts from the kraft pulping process is shown in Figure 1 (see next page).

Tall Oil Precursor in Pine Wood. Exploitation of the original tall oil materials in pine wood in the form of products such as tar and pitch dates from centuries B.C. Gum and wood rosin are still produced, and compete with the rosin fraction, TOR, derived from CTO.

Products such as gum rosin (residue product, → Resins, Natural, Chap. 5.2.1.), and turpentine

oil fractions (→ Turpentines) (distillates) obtained by distillation of exuded oleoresin from wounded living trees are still of high volume and importance. However, gum rosin production in the United States has declined drastically from ca. 300 000 t/a in 1930 to almost zero today owing to the lack of affordable labor. Despite this fact, worldwide gum rosin production in the early 1990s has been reported to be as high as 700 000 t/a. The People's Republic of China alone reports 400 000 t/a. Extraction of products such as wood rosin and turpentine fractions from stumps rich in rosin and liquid gum has declined because of the shortage of stumps (→ Resins, Natural, Chap. 5.2.2.).

Replacement of Original Products by Tall Oil. The production of CTO as a byproduct of the kraft pulping process and the subsequent refining of CTO have supplied important and renewable resources such as tall oil rosins and tall oil fatty acids as two basic chemical raw materials. The decreasing supply of wood and gum rosin in the United States is well compensated by the TOR production, which has increased proportionally to pulp production (see Fig. 2).

Tall Oil in Wood. The extractable portion of wood differs chemically, in part, from the compounds found in the CTO product. The chemical changes occurring during various processing steps are shown in Figure 3. Examples of composition of the extract from different wood species are listed in Table 1.

Table 1. Composition of the extract from different wood species

Compounds	Pine	Spruce	Birch

Total, %	92	78	64

2.1. Composition and Properties of Crude Tall Oil

The wide range of compositions and properties of crude tall oil on the market can be explained and understood from the chemistry of tall oil. Many tall oil components are sensitive to chemical reactions and changes in properties and composition. The use of wood species other than pine [e.g., spruce and hard wood (birch)] in the kraft pulping process lowers the yield of CTO and the selection of available fatty and rosin acids. It also changes the composition and properties of the CTO. The quality and yield of CTO from

Figure 2. Historical development of global production of tall oil materials
A) CTO; B) Wood rosin; C) Gum rosin; D) Tar

the kraft pulping process consequently depend on many variables such as type and length of wood storage, season of the year, amount of wood residue used, hardwood usage, and type of pulping employed.

Table 2. Primary constituents of tall oil in different wood species

	Extractives, %	Fatty acids, kg/t wood	Rosin acids, kg/t wood	Unsap ∗, kg/t wood
Pine	≈ 3	15 – 20	5 – 10	2 – 5
Spruce	≈ 1	4 – 8	1 – 2	1 – 3
Birch	≈ 2	12 – 18		5 – 10

∗ Unsaponifiables.

Crude tall oil is a dark brown, tarlike product; its odor, influenced by sulfur components from pulp processing and soap skimming/acidulation, is unpleasant and penetrating. The three main constituent groups – fatty acids, rosin acids, and neutral materials (unsaps) – vary widely in composition, depending on the wood's origin (see Table 2). The saponification number (SN) of CTO is always higher than the acid number (AN) because of the unsplit esters in the crude oil. The difference increases for lower qualities, indicating less available rosin and fatty acids.

The crude is normally transported and stored at 50 – 80 °C to avoid crystallization and settling of rosin acids. The viscosity of the crude is variable; it is mainly a function of the rosin content. Viscosity must be measured on a clear, noncrystallized product. Impurities such as lignin, soap residue, water – oil emulsions, sodium salts, and sulfuric acid occur in the product. The amount of these undesirable materials depends on the efficiency of the soap washing and splitting process. Sour components such as sulfuric acid in the separated brine and degassed sour vapors from heated CTO in storage tanks impart the crude corrosive properties. The physical properties of tall oil (empirical values) are listed below:

Liquid viscosity (at 70 °C)	25 – 40 mm^2/s

Typical data and composition of crude tall oil are presented in Table 3.

2.2. Recovery of Soap and Conversion to Crude Tall Oil

During the kraft pulping process, CTO precursors are hydrolyzed to soluble sodium soaps in the cooking liquor. The soap and spent cooking liquor (black liquor) are washed and filtered from the pulp and concentrated in multipleeffect evaporators from 13 – 15 % to > 65 % solids. Evaporation increases the solids content so much that the soap – contaminated with black liquor to a greater or lesser extent – precipitates and rises continuously to the surface of the upgraded liquors in skimming tanks connected to the evaporation process. When the soap is skimmed from the top of the black liquor tanks, contamination of the soap with some black liquor is unavoidable. The major part of this black liquor containing about 10 % lignin should be removed. Otherwise, precipitation of the lignin and gypsum (gypsum is formed because of the presence of calcium in the black liquor) will occur during subsequent acidulation. Good decantation or separation of the soap is thus important. A low black liquor content of the soap decreases acid consumption and the amount of toxic hydrogen sulfide and carbon dioxide released during acidulation. In addition, soap present in black liquor and in the heavy black liquor (i.e., concentrated black liquor) decreases the capacity of both the evaporator system and the recovery boiler.

The *splitting* or *acidulation process* is a chemical reaction between the sodium soaps and sulfuric acid. The tall oil soap is converted into free fatty and rosin acids by reaction with dilute sulfuric acid (ca. 30 %) at elevated temperature (ca. 98 °C). The reaction can be summarized as follows:

$$2\,RCOONa + H_2SO_4 \longrightarrow Na_2SO_4 + 2\,RCOOH$$

where R denotes a rosin or fatty acid alkyl group.

Three phases are formed during the reaction: liberated tall oil, a lignin – fiber phase, and the spent acid phase (Na_2SO_4, free H_2SO_4). The phases can be separated because of their different densities. The splitting process is performed

either batchwise or continuously. In both cases the equipment must be made of acid-proof material, able to resist dilute sulfuric acid (spent acid or brine) at 90 – 100 °C. A pH of 2.5 – 3.5 is normal for complete reaction with a minimum of equipment corrosion. The Hedemora – Celleco continuous tall oil system is shown in Figure 4.

2.3. Upgrading of Soap Extraction (Crude Soap Refining Process)

On a limited scale, crude birch – pine soap is upgraded by extraction of neutrals before acidulation. The crude soap refining (CSR) process developed by Holmbom and Avela in Finland yields not only a cleaner CTO but also commercial compounds such as sitosterols, terpenes, and aliphatic alcohols from the extracted neutrals. This upgrading process has been in operation since 1977 (Kaukas, Finland).

3. Upgrading of Crude Tall Oil by Distillation

History. In 1930 – 1950 a number of relatively small distillation plants (< 10 000 t/a) came onstream in Scandinavia and the United States, producing rosin-rich distillates and distilled tall oil. The "rosin oil" fractions were crystallized and centrifuged. The rosin crystals (rosin acid content ≈ 90 %) were melted and partly saponified.

The amorphous *rosin product* replaced gum and wood rosin in Scandinavia and was used in the Delthirna process for making paper size. The *distilled tall oil fraction* (rosin acid content 20 – 30 %) – in Scandinavia named "såpolja" (soap oil) – was used to make laundry soaps, as gel and solid products.

The introduction of *Linder trays* in fractionation towers was a promising alternative to already existing "dry" distillation (randomly packed) column processes. The first Linder plant came onstream in 1947 at Mo och Domsjö, Sweden as a dry distillation process designed for a rosin fraction introduced at the bottom of the column. The tall oil flow followed a convoluted path through a series of trays, encountering vapors generated in an electrically heated reboiler at the bottom of the column. Later, several Linder plants came onstream, further developed to produce TOFA with a low rosin content.

In 1949, Arizona Chemical and E. R. Badger introduced a *"wet" distillation process* in the United States, based on the experiences and techniques of the petroleum industry. This dis-

Figure 5. Sulzer's structured packing

tillation differed from the Scandinavian process. The use of bubble-cap towers for distillation made the addition of steam necessary for vaporization of the high-boiling tall oil components. To achieve sufficient separation of the fatty and rosin acids, a considerable number of trays is required. To overcome the high static pressure drop in the column, sparge steam must be used to avoid undesirable reactions of the products, caused by too high boil-up temperatures. Initially, the Arizona plant came onstream as a two-pass operation in a two-column system. The feed of the first pass is CTO, that of the second the crude fatty acid fraction from the first pass.

In 1970, Luwa, Switzerland built a plant for Krems Chemie in Austria using Luwa *thin film evaporators* for dehydration, depitching, and heat exchange for boil-up in the fractionation tower (packed columns). This approach minimized the time during which heat-sensitive compounds in tall oil were exposed to elevated temperature.

The introduction of *large-scale structured packing* (Mellapak, Sulzer Chemtech, Switzerland, see Fig. 5) at the Bergvik plant in 1979 improved the efficiency and capacity of the towers to achieve more complete fractionation of the vaporized high-boiling compounds in CTO. Worldwide, approximately 15 – 20 rosin columns and approximately 10 – 20 fatty acid columns equipped with structured packings are onstream today. A capacity comparison of two equal rosin columns, one of which is equipped with structured packing (Mellapak), is given in Table 4.

Table 4. Comparison of the capacity of two equal rosin columns

Characteristic	Pallring/minirings	Mellapak
Top pressure, kPa	0.2	0.2
Bottom pressure, kPa	1.6 – 2.0	0.8 – 1.2
Bottom temperature, °C	270 – 280	255 – 265
Capacity, t/a	40 000	80 000
Reflux ratio	4	2

3.1. Technical and Economic Conditions

Lengthy development work was required from the time CTO was discovered until a scientifically designed distillation process was achieved. Process performance may differ depending on local conditions, CTO quality, capacity demand, operation control equipment, and in-plant experiences, but the technology advances introduced have resulted in plants all over the world that are capable of producing fatty and rosin acid fractions of very high purity and quality. Special arrangements – mainly for the rosin fraction – were necessary because of variations in the quality of the CTO. However, these changes enabled the production of fractions with specific composition and properties. In practice, distillation of CTO has been achieved in two ways, both carried out in vacuum and at elevated temperature. The

Figure 6. Vapor pressure curves of tall oil components (log p – $1/t$ curves, t in °C is depicted on $1/t$ axis for convenience)
a) Caprylic acid ($C_8H_{16}O_2$); b) Capric acid ($C_{10}H_{20}O_2$); c) Lauric acid ($C_{12}H_{24}O_2$); d) Myristic acid ($C_{14}H_{28}O_2$); e) Palmitic acid ($C_{16}H_{32}O_2$); f) Oleic acid ($C_{18}H_{34}O_2$); g) Stearic acid ($C_{18}H_{36}O_2$); h) Arachidic acid ($C_{20}H_{40}O_2$); i) Abietic acid ($C_{20}H_{30}O_2$); j) Behenic acid ($C_{22}H_{44}O_2$); k) Heavy neutrals
(Courtesy of Sulzer Chemtech AG)

high-boiling components of tall oil can be vaporized either in the presence of superheated steam (wet process) or without adding any steam at all (dry process). In both cases, low pressure is necessary to vaporize the high-boiling compounds. At actual operating temperature the compounds are sensitive to undesirable chemical reactions, depending on heating conditions. In addition, the compounds degrade rapidly in the presence of oxygen. Therefore, the entire apparatus involved in distillation must have the functional security sufficient to meet the demand of steady running.

The "dry" process is more favorable today than the "wet process"; it involves lower energy costs and less air and water pollution. The Swiss technology – rapid heating for boil-up and improved mass transfer at lower pressure drop and lower reflux ratios – for distilling CTO has been successful and used completely or partly in new and upgraded plants all over the world.

The trend in the tall oil field has been toward increased capacity, in order to gain scaleup effects, meet pollution restrictions, and produce tall oil fractions that are suitable for further processing into specific products. To obtain this, computerized control facilities are generally necessary and of great importance. Most of all, a stable operating pressure (vacuum) must be maintained to obtain fractions that meet certain values and limits. Even a small pressure change results in different process temperatures, corresponding to the new pressure. Improved techniques and resistant materials, more suited for treatment of high-boiling and heat-sensitive tall oil compounds, have led to the development of efficient distillation processes. The vapor pressure curves of tall oil components are depicted in Figure 6. The residence time of the product and the temperature differences between the product and the heating medium in different reboilers (see Table 5, next page) influence product quality and yield. Therefore, heating conditions are very important.

As heating medium Dowtherm (→ Hydrocarbons) is often used in liquid form. The desired or programmed product temperature and

Figure 7. Simplified flow sheet for large-capacity plants (>100 000 t/a)
a) Dehydration; b) Depitcher; c) Rosin column; d) Light ends column; e) Fatty acid column; f) Distilled tall oil columns

composition can be established with great precision at each heating station by regulating the amount of Dowtherm liquid flow in the loops connected to the head coil.

Dowtherm in vapor form as heating medium is still used mainly in U.S. plants, in a way similar to conventional steam-heated systems.

The principal flow sheet for the tall oil distillation process is, in practice, quite old. A simplified flow sheet of a large-capacity plant (> 100 000 t/a) is given in Figure 7. The Bergvik Kemi tall oil plant is shown in Figure 8.

Table 5. Residence time and Δt (temperature difference between heating medium and product) for different types of reboiler

Type of reboiler	Residence time	Δt, °C
Forced circulation	≈ 60 min	≈ 5
Thin-film evaporator with fixed wipers	≈ 5 s	≈ 40
Falling-film evaporator with circulating pump	1 – 2 min	≈ 15

Figure 8. Bergvik Kemi tall oil plant

3.2. Process Description

3.2.1. Dehydration

CTO is fed directly from the storage tank into the thin-film evaporator (Fig. 7, a) for rapid preheating up to 200 °C under vacuum (3 – 6 kPa). Inert combustible gases, water (≈1 %), low-boiling compounds such as organic heads (H_1) and turpentine (≈1 %) are distilled during the first passage through the evaporator. This operation makes possible a stable low pressure (≈ 0.3 kPa) in the dry distillation and fractionation of the relatively high-boiling tall oil components that follow.

3.2.2. Depitching

The applicability of dry distillation not only is influenced by the CTO composition but is also highly dependent on conditions [e.g., operating pressure and temperature and residence time of the products in the depitcher (Fig. 7, b)].

The vaporization and squeezing of vaporizable products, such as separation of the fatty and rosin acids from native pitch compounds in CTO and from pitch formed by heating, require a high temperature (270 – 275 °C), even at low pressure (800 – 1300 Pa), measured at the vapor entrance into the rosin column or the first fractionation tower. The optimal depitching conditions for obtaining maximum yields and purity of rosin and fatty acid fractions are, however, of delicate nature. At elevated temperature undesirable reactions can occur such as esterification of fatty acids (by alcohols contained in the CTO), polymerization, decarboxylation of rosin acids, and isomerization of abietic-type acids. Too high a depitching temperature also leads to decomposition and vaporization of high-boiling compounds (neutrals, fatty acids) that affect the quality of rosin and fatty acid fractions negatively.

3.2.3. Fractionation of Vaporized Tall Oil Compounds

To reduce the pressure drop and achieve the lowest possible pressure in the depitching step the top section of the rosin column has a wider diameter than the lower section. Overhead vapor from the depitcher, consisting mainly of rosin and fatty acids but also of nonacidic compounds, is fed to the rosin column (Fig. 7, c) to recover rosin as a bottom fraction (TOR). The rosin acids in TOR are similar in composition to those found in gum and wood rosin. As distillate (side stream from the upper part of the column) the crude fatty acid intermediate fraction, containing about 8 % rosin acids, is taken off and fed to the light ends column (d) to remove light heads (a mixture of neutral compounds and short-chain fatty acids). The bottom fraction, containing mainly C_{18} fatty acids, a smaller portion of rosin acids, and a "minimum" of neutrals, is then fed to the fatty acids column (e) for production of high-quality tall oil fatty acids as a side stream from the top section of the column. From the top of all involved fractionation towers, smaller cuts of head fractions containing mixed neutrals and "low-boiling" ($C_8 - C_{16}$) fatty acids are distilled off ($H_1 - H_4$).

Distilled tall oil containing most of the rosin acids in the intermediate or crude fatty acid fraction, is usually distilled off as a side stream "middle-boiler" fraction as well as by other means, depending on local technical conditions and feed composition.

The fatty acids in CTO are mainly C_{18} unsaturated acids (≈ 85 %) in which a significant proportion of the linoleic acid has been isomerized to the conjugated acid during the alkaline pulping process. The rest of the fatty acids are – if compared to the C_{18} compounds – of "low-boiling" and "high-boiling" character. More than 20 different acids from C_8 to C_{24} have been identified, among which palmitic, stearic, eicosanoic, arachidic, and behenic acids are of most interest. The higher-boiling fatty acids are concentrated mainly in the DTO fraction by fractional distillation, but are also contaminants in the rosin acid fraction. Depending on the conditions during pulping and distillation, some abietic types are isomerized to dehydroabietic acid.

Both the tall oil fatty acids and the rosin acids contain two functional groups: double bonds and the carboxyl group, which allow a number of chemical reactions. Some of these occur during processing, depending on CTO composition and external physical and chemical influences. These reactions result in increased pitch yield (by esterification, polymerization, oxidation) or

Table 6. Principal composition and yields of tall oil fractions and some empirical volatility data

Fraction	Yield, %	Acid number	Composition, %		
			Rosin acids	Fatty acids	Neutrals
Head	5 – 12	70 – 120	<0.5	30 – 50	40 – 60
TOFA	35 – 45	192 – 197	<2	95 – 98	1 – 2
DTO	5 – 15	180 – 190	20 – 30	65 – 70	4 – 7
TOR	20 – 35	165 – 182	85 – 96	1 – 5	1 – 7
TOP	20 – 40	20 – 50	5 – 13	5 – 10	40 – 60

affect the molecule structure of certain sensitive materials (e.g., isomerization of linoleic acid in the fatty acid group). Levopimaric acid is converted to more stable forms, and other isomers of abietic acid are formed.

The principal composition and yields of tall oil fractions are listed in Table 6.

4. Energy Recovery

Like many other distillation processes characterized by several steps and elevated temperature (150 – 300 °C), the energy demand of tall oil distillation is large and costly. Thus, operating the distillation column at low reflux ratios and reusing the energy from the condensation system as heat (i.e., for the distillation process and for supplementary equipment, tanks, etc., belonging to a complete tall oil plant) is very important in terms of economics.

Besides the usual arrangements for heat exchange of hot and cold streams in the process, most of the thermal energy from the condensation system can be transformed into low-pressure steam (see Fig. 9). The quantity of low-pressure steam in principle meets the demands of the tall oil process. It is used mainly in vacuum jets and CTO tanks but also for other heating purposes.

5. Security and Construction Material

Acceptable construction material and process equipment that resist the corrosivity of tall oil compounds – particularly fatty acids – ensure reliable operation. Based on many years of "dry" distillation, the Co – Ni – Mo alloy, containing 2.5 % molybdenum (AISI Type 316) was regarded as an acceptable material, combating cor-

Figure 9. Heat recovery system

rosion generally in the tall oil distillation process. However, as time went on, the corrosion of replacement parts occurred, sometimes followed by unscheduled shutdowns and quite often fires. This resulted in the use of an alloy containing more than 3.5 % molybdenum (AISI Type 317).

Vapor-phase streams are more corrosive than liquid-phase streams, and corrosion increases with increasing temperature. The corrosion rate of alloys with 5 – 6 % molybdenum is negligible; thus, the use of high-molybdenum alloy in construction of the equipment is essential. Aluminum has been used for tanks, pipelines, packings, etc., and is still of interest when special strength is not required.

6. Analysis

Most of the analytical methods for tall oil are established standards and, as such, collected in ASTM and especially in SCAN (Scandinavian Pulp Paper Testing Committee) publications. About 20 standard methods are available.

Figure 10. Gas chromatogram of tall oil rosin
1. Pimaric acid; 2. Sandaracopimaric acid; 3. Palustric acid; 4. Isopimaric acid; 5. Abietic acid; 6. Dehydroabietic acid; 7. Neoabietic acid

In addition to the standard methods of analyses, gas – liquid chromatography, mass spectroscopy, and gel permeation chromatography are used widely for better understanding of tall oil chemistry. A gas chromatogram of tall oil rosin is shown in Figure 10. These methods are essentially necessary complements to the older standard analyses for further development of the processes and of special or unique products as well. Typical data and composition of tall oil fatty acids and of tall oil rosins are listed in Tables 7 and 8.

7. Storage and Transportation

The crude tall oil, melted rosin, and pitch are stored at elevated temperature to reduce viscosity. Air exposure of both fatty and rosin acid fractions results in darkening of the products. Protection with inert gases – N_2, CO_2, and steam – at elevated temperature is recommended. The fatty and rosin acid fractions are preferably stored and shipped in tanks made of stainless steel or aluminum. When rosin in the melted state is shipped in insulated tank cars, the temperature is kept at $> 160\,°C$. Rosin derivatives should be produced in direct connection with the distillation process. By storing rosin in solid form (galvanized drums), additional costs (packaging, handling, remelting, etc.) may arise. In addition, TOR in drums can crystallize easily to become nonbrittle and often difficult to remove. Today, the modified resin products are generally flaked or compressed into tablets and delivered in paper bags.

8. Uses

Uses of CTO. Most of the world production of CTO ($\approx 1.5 \times 10^6$ t/a) is utilized as raw material in continuous distillation processes, producing high-quality tall oil fatty acid fractions and tall oil rosins as primary products. If the CTO is "low grade" (e.g., the content of valuable components is too low), the product (or the corresponding soap) is used as liquid (or solid) fuel. Since CTO, irrespective of quality, can always be used as a fuel oil, its minimum price is more or less related to actual "fuel oil" prices on the market, including taxes and other associated costs.

Tall Oil Fractions. The TOFA and TOR fractions are used widely for further processing into a variety of chemical products, replacing other raw materials such as gum and wood rosin, hydrocarbon resins, and vegetable oils. Improved distillation techniques have led to upgraded fractions of TOFA and TOR that are attractive raw materials for special chemicals. The chemical structure of some fatty and rosin acids makes the primary tall oil fractions suitable as raw material for making intermediate chemicals. Examples are the production of dimeric fatty and rosin acids, polymerized rosin, and maleic and fumaric anhydride (acids) – rosin adducts including their salts and esters (→ Resins, Natural, Chap. 5.5.). The dimeric acids are utilized as raw materials to make products used in adhesives, coatings, inks and epoxy resins. Most of the intermediate chemicals are processed in

the presence of certain catalysts. An overview of the applications of tall oil fractions is given in Table 9.

9. Economic Aspects

The total world production of CTO was in the range of 1.5×10^6 t in the early 1990s. Most of the available quantities are produced and refined in the United States and Europe. The world tall oil fractionation capacity by region is as follows:

United States	56 %
Scandinavia	21 %
Other Western Europe	7 %
Other	16 %

A breakdown of world tall oil fractionation capacity by company is given in Figure 11.

10. Toxicology and Environmental Protection

Toxicology. The tall oil compounds in living trees, stumps, CTO, fractions, etc., are nonhazardous natural substances. Modified tall oil products and solutions may, however, become hazardous because of the chemicals and solvents used. Many tall oil derivatives such as glycerol and pentaerythritol esters, alkyd resins, dimerized fatty acids, and rosin acids are generally regarded as nonhazardous products.

The toxicity of tall oil components in effluent water to fish is not a function of oxygen demand. Fish may tolerate some higher (allowed) concentration limits of rosin and fatty acids or their sodium soaps in the waste stream. These concentrations may be indicated along with the other conventional parameters (COD, BOD, etc.) of the wastewater.

Environmental Protection. During vacuum distillation, some product losses arise, resulting in polluted water and inert gases. The water streams from the various processes are of different compositions but after passing through special oil separation equipment, they are collected for the removal of organic waste constituents by biological, physical, or chemical methods before they are discharged (see Fig. 12). The noncondensed (odor) component of the gases may be disposed of as fuel gas if necessary.

The dry distillation method has the advantage of requiring fewer measures to combat pollution compared to the wet process. In distillation, most of the polluted water comes from the dehydration steps, where the "low-boiling" components (1 %) together with the water in CTO (1 %) are distilled off from the feed before depitching. Additional sources of polluted water are related to the steam jet vacuum systems, plant cleanup wastes, CTO storage tanks, pumps, etc.

1. Introduction

Tantalum, Ta [*7440-25-7*], atomic number 73, relative atomic mass 180.948, has the electronic structure $1s^2$, $2s^2p^6$, $3s^2p^6d^{10}$, $4s^2p^6d^{10}f^{14}$, $5s^2p^6d^3$, $6s^2$, which accounts for its principal oxidation states +2 and +5. There are two naturally occurring isotopes: ^{181}Ta and the weakly radioactive isotope ^{180}Ta (0.012 %, half-life ca. 10^{13} years). A large number of artificial radioactive isotopes are also known.

Tantalum was discovered by EKEBERG in 1802 [1,2]. The discovery and history of tantalum and niobium are closely linked (→ Niobium). The two elements usually occur together.

2. Properties

2.1. Physical Properties

The physical properties of tantalum are as follows [1–7]:

Crystal structure	Body-centered cubic
Lattice constant	$a = 0.33025$ nm
Density	16.6 g/cm^3
Melting point	2996 °C
Boiling point	5425 °C
Heat of fusion	28.5 kJ/mol
Heat of vaporization at 3273 K	78.1 kJ/mol
Specific heat capacity at 20 °C	25.41 J mol^{-1} K^{-1}
Linear coefficient of thermal expansion at 20 °C	6.5×10^{-6} K^{-1}
Thermal conductivity at 20 °C	54.4 W m^{-1} K^{-1}
Specific electrical conductivity at 20 °C	0.081 Ω^{-1} cm^{-1}
Superconductivity	4.3 K
Temperature coefficient (0 – 100 °C)	0.00383

The effect of temperature on electrical and thermal conductivity has been accurately determined [3].

The mechanical properties of the metal are strongly dependent on its purity, structure, and crystal defects, as is the case with almost all refractory metals. Even low concentrations of interstitial impurities increase the hardness and reduce the ductility. The yield strength is strongly temperature dependent, the value at 200 °C being ca. 30 % of that at 20 °C [3]. The important mechanical properties are as follows [1,3,7,8]:

Tantalum, soft annealed	
Tensile strength	240 MPa
Yield strength (0.2 % offset)	210 MPa
Breaking elongation	40 %
Vickers hardness	60 – 120 HV
Modulus of elasticity	177 – 186 MPa
Ductile – brittle transition temperature	4 K
Poisson's ratio	0.35
Tantalum, cold formed	
Tensile strength	400 – 1400 MPa
Yield strength (0.2 % offset)	300 – 900 MPa
Breaking elongation	2 – 20 %
Vickers hardness	105 – 200 HV
Recrystallization temperature	1200 – 1500 K

2.2. Chemical Properties

Like niobium, tantalum has principal oxidation states +2 and +5. Below 100 °C, tantalum metal is extremely resistant to corrosion by most organic and inorganic acids, with the exception of hydrofluoric acid. This is due to a dense adherent film of tantalum oxide, a characteristic which is utilized in the manufacture of electrolytic capacitors (Section 5.3). Above ca. 300 °C, tantalum tends to form oxides, nitrides, hydrides, and carbides. All modern tantalum capacitor powders can be handled in air at temperatures up to ca. 100 °C. However, they are classified as flammable solids as they ignite at higher temperatures, forming Ta_2O_5.

3. Occurrence

Tantalum is 54th in order of abundance of the elements in the Earth's crust (2.1 g/t). In many deposits, it occurs in association with the much more abundant niobium (24 g/t). The most important tantalum-containing minerals are tantalite, wodginite, microlite (the tantalum-rich end member of the pyrochlore series), and columbite [9]. The typical Ta_2O_5 concentration in processable pegmatitic deposits, which represent the principal raw material potential, particularly in Australia, is < ca. 0.1 %. The uranium- and thorium-containing minerals yttrotantalite, strueverite, euxenite, and samarskite are sometimes highly radioactive, which limits their workability [10]. An important potential reserve lies in a belt stretching from China to Indonesia via Thailand and Malaysia, and consists of cassiterite (SnO_2) that contains some tantalum and niobium. During tin smelting, the tantalum and niobium become concentrated in the slag (→ Niobium, Chap. 4.3.1.). The important deposits, with estimated current production capacities, are listed in Table 1, and the compositions of some tantalum-containing minerals are given in Table 2.

Table 1. Tantalum deposits [11–15]

Location	Reserves, 10^3 kg Ta_2O_5	Production (1991, estimated), 10^3 kg Ta_2O_5	Annual production capacity (estimated), 10^3 kg Ta_2O_5
Australia	17 000	235	300
Brazil	18 000	100	245
Canada	3 000	80	130
Malaysia	2 000	80	130
Thailand	16 000	150	200
Africa	10 000	25	50
Russia	> 20 000	< 50	
China	17 000	100	200
Others	10 000	< 50	< 100

4. Extraction

4.1. Extraction and Processing of Ore Concentrates

In the important Australian mines, the tantalum-containing minerals are present in finely divided form in hard pegmatitic rock. The rock is extracted by open-cast mining. Further processing, which is different from that used for the mainly niobium-containing deposits (→ Niobium and Niobium Compounds, Chap. 4.), is an initial size reduction to < 15 mm, followed by grinding in ball or rod mills to < 1 mm. Flotation is then carried out, and the soluble constituents are leached out from the concentrates. The latter are then dried, and the magnetic constituents are removed [18].

Table 2. Composition of important tantalum-containing minerals [9, 16, 17]

Mineral	Composition	Ta_2O_5 content, %	Nb_2O_5 content, %
Tantalite	$(Fe, Mn)Ta_2O_6$	42 – 84	2 – 40
Microlite	$(Na, Ca)(Ta, Nb)_2O_6F$	60 – 70	5 – 10
Columbite	$(Fe, Mn)(Nb, Ta)_2O_6$	1 – 40	40 – 75
Wodginite	$(Ta, Nb, Sn,, Fe, Mn)_{16}O_{32}$	45 – 56	3 – 15
Yttrotantalite	$(Y, U, Ca)(Ta, Fe^{3+})_2O_6$	14 – 27	41 – 56
Fergusonite	$(RE^{3+})(Nb, Ta)O_4$ *	4 – 43	14 – 46
Strueverite	$(Ti, Ta, Nb, Fe)_2O_4$	7 – 13	9 – 14
Tapiolite	$(Fe, Mn)(Nb, Ta)_2O_6$	40 – 85	8 – 15
Euxenite	$(Y, Ca, Ce, U, Th)(Nb, Ta, Ti)_2O_6$	1 – 6	22 – 30
Samarskite	$(Fe, Ca, U, Y, Ce)_2(Nb, Ta)_2O_6$	15 – 30	40 – 55

* RE = rare earth element.

Figure 1. Major tantalum processing routes

This ore concentrate, up to 40 % Ta_2O_5, is dissolved in concentrated hydrofluoric acid (→ Niobium and Niobium Compounds, Chap. 4.3.), and is then separated from the niobium by extraction with methyl isobutyl ketone, so that the tantalum is obtained as H_2TaF_7. Potassium salts are added, and potassium heptafluorotantalate, K_2TaF_7 [*16924-00-8*], crystallizes out. This is reduced with sodium to metallic tantalum (Section 5.1).

Major tantalum processing routes are summarized in Figure 1.

4.2. Obtaining Ta – Nb Concentrates from Tin Slags

Tantalum-containing tin slags represent an important source of tantalum; e.g., in 1980, ca. 50 % of world demand was recovered from tin slags [19–21]. Owing to the low price of tin, its production is in continuous decline, so that the availability of tantalum-containing tin slags is decreasing. Moreover, the tantalum concentration in tin concentrates is also decreasing significantly. The fraction of the world demand for tantalum represented by Ta_2O_5 in tin slags is expected to fluctuate around 20 %. The price of tin is not likely to reach a level at which more tantalum-rich tin ores from Thailand and Malaysia can be processed economically.

The tantalum content of these slags fluctuates widely. Bolivian slags do not contain tantalum, but those from Thailand can have tantalum content 15 – 16 % Ta_2O_5. The Ta:Nb ratio varies from 1:0.4 (Thailand) to 1:3 (Nigeria).

The most important grades of slag have the following tantalum and niobium content [19–21]:

	Ta_2O_5, %	Nb_2O_5, %
High-grade		
Thailand	13 – 16	9 – 10
Zaire	11	10
Australia	10	5 – 6
Medium grade		
Thailand	4 – 5	4
Malaysia	3 – 4	3 – 4
Nigeria	4 – 5	12
South Africa	6 – 8	8 – 9
Low-grade		
Malaysia	0.8 – 2.5	0.8 – 2.5
Thailand	0.5 – 1	0.2 – 0.8
Brazil	1 – 2.5	1 – 2.5
Singapore	1 – 1.5	1 – 1.5

High- concentration slags are used directly in the wet chemical process (dissolution of the slag in hydrofluoric/sulfuric acid, followed by extraction and separation of tantalum and niobium).

From low- concentration slags, Ta/Nb concentrates containing 50 – 60 % Ta_2O_5/Nb_2O_5 can be produced, e.g., pyrometallurgically. The Ta/Nb content of these synthetic concentrates is > 99 % soluble in hydrofluoric acid, as is the case with natural ores.

In all the concentration processes so far developed, the slag is first melted in an electric furnace with addition of reducing agents, e.g., coke, and fluxing materials. This causes the Ta/Nb to collect in the carbide- containing ferroalloy produced, while some impurities remain in the slag. The solid ferroalloy is produced in relatively large blocks, which must be broken up and ground. The tantalum/niobium content is increased in further process steps, giving a concentrate containing 50 – 60 % oxides of tantalum and niobium.

One method of enriching the tantalum and niobium consists of oxidizing the ferroalloy, which contains the Ta/Nb carbide, with Fe_2O_3 (e.g., as hematite). This causes undesired elements to be collected in the oxidic slag, while the Ta – Nb carbide is oxidized only as far as the metals and therefore remains in the metallic phase. In a final reaction stage, this is again oxidized with Fe_2O_3 to form a slag that contains tantalum and niobium oxides [22].

The partial oxidation can also be carried out in a single smelting stage using air, oxygen-enriched air, or pure oxygen. Under these conditions, the tantalum is converted to slag much more rapidly than the niobium, enabling the tantalum to be concentrated at the expense of niobium [23]. Ta/Nb carbide- containing ferroalloy can also be treated by wet leaching processes [24–26].

4.3. Processing Tantalum Scrap

When processing tantalum- containing waste materials, physical and chemical processes are used as much as possible, avoiding processes typically used in ore treatment, i.e., dissolution in hydrofluoric acid and solvent extraction. The tantalum scrap is divided into two categories which differ in difficulty of recycling:

1) Scrap material of the first type can consist of pure unoxidized metallic tantalum, e.g., sintered tantalum powder pellets (anodes) from the manufacture of tantalum electrolytic capacitors, scrap foil, sheet, and wire, or of anodically oxidized sintered tantalum pellets containing 1.5 – 3 % oxygen from capacitor manufacture and oxidized wire scrap arising from this process.
   The following processing methods are commonly used for these scrap materials: ingot melting in an electron beam furnace, or conversion to brittle tantalum hydride, grinding, and dehydrogenation at > 600 °C in vacuo or under a protective gas to form metallic tantalum powder [1]. Alternatively, the ground tantalum hydride can be carburized with carbon black to form tantalum carbide [27].
   The oxygen content of oxidized tantalum anodes can be reduced by deoxidation with magnesium or calcium to give high-grade scrap [28].
2) Scrap of the second type consists of oxidized tantalum anodes coated with manganese dioxide or with conductive silver, or sometimes welded to nickel conductor wires. This category also includes faulty capacitors, in which the coated and welded tantalum anodes also have an encapsulation of synthetic resin or tinned brass.
   Pure oxidized tantalum anodes can be recovered from coated anodes and brass-encapsulated capacitors by successive treatments with nitric and hydrochloric acid. Resin- encapsuled capacitors require complex treatment. These can be coarsely size-reduced in grinding mills, the tantalum being recovered by density separation. Foreign metals are removed by treatment with nitric and hydrochloric acid, leaving a residue of oxidized tantalum anodes in granular form [29].
   Another method has been described for the treatment of tantalum anode scrap containing manganese dioxide. This can be directly reduced in an argon/hydrogen plasma and melted to pure tantalum [30]. If the scrap capacitor materials are resin free, the tantalum can be recovered as its pentachloride by chlorination [31].

Some types of tantalum scrap which contain other impurities are roasted to form the oxide, and treated like ore concentrates. These include condensates formed during the melting of tantalum ingots, scrapped alloy materials, impure sawings and turnings, flue dust, and sediments from the wash liquors from the sodium reduction of potassium heptafluorotantalate.

Hard metals that contain tantalum carbide can be attacked by roasting and treating with caustic soda solution [32], anodic oxidation [33], or melting with sodium nitrate [34], converting the tantalum to its oxide for further recovery treatment.

5. Metallic Tantalum

5.1. Production

Metallic tantalum products (powder, semifinished products, ingots) are produced almost exclusively by reduction of potassium heptafluorotantalate with sodium [35,36]:

$$K_2TaF_7 + 5\,Na \longrightarrow 2\,KF + 5\,NaF + Ta$$

The strongly exothermic reaction is controlled by adding inert salts (KCl, NaCl, KF, NaF). The reduction can be carried out at constant temperature by controlled addition of one of the reactants, with controlled heat removal. Tantalum powder is recovered by leaching the salts out of the reaction product. Two processes are commonly used to obtain tantalum capacitor powder from this:

1) The sodium-reduced metallic tantalum powder is purified and converted to a compactable and free-flowing product by further processing stages, e.g., high-temperature treatment in vacuo or under protective gas, deoxidation by magnesium [37], or a combination of these two processes [38]. Optimum properties for capacitor production are obtained by the addition of dopants to control sintering of porous pellets [39–41].
2) During ingot melting of compressed slugs of tantalum powder in electron beam or electric arc furnaces [42], volatile impurities are driven off, usually in two smelting operations. The ingot can be ground after hydrogenation. The powdered tantalum "hydride" is then dehydrogenated in vacuo [1] and agglomerated by high-temperature treatment.

In addition to the sodium reduction process, other processes have been described, i.e., the molten salt electrolysis of K_2TaF_7 with addition of Ta_2O_5 or $TaCl_5$, and hydrogen reduction of $TaCl_5$ [1,43], but these have not achieved economic importance. The carbothermic reduction of Ta_2O_5 in high vacuum [1,4,44] at ca. 1900 °C leads first to tantalum carbide:

$$Ta_2O_5 + 2\,C \longrightarrow 2\,TaC + 5/2\,O_2$$

This reacts above 2000 °C with residual Ta_2O_5 to metallic tantalum:

$$5\,TaC + Ta_2O_5 \longrightarrow 7\,Ta + 5\,CO$$

Because of the high quality standards for particle size and purity required by the producers of tantalum capacitors (Section 5.3), this process is of minor importance.

5.2. Semifinished Products

Tantalum metal powder for producing semifinished products is also obtained by reducing K_2TaF_7 with sodium. Semifinished products such as sheet, wire, and shaped articles are produced by two different methods:

1) Powders are compacted, and then sintered by passing an electric current at ca. 2500 °C (Coolidge process) or indirectly by resistance or induction heating in vacuo. Tantalum wire for tantalum electrolytic capacitor manufacture is produced by this process. It is advantageous to control the grain size, e.g., by adding dopants [45], to optimize the mechanical properties.
2) Bars produced by powder compression are formed into ingots by electron beam or electric arc melting, and shaped by forging, rolling, extruding, and wire drawing. Intermediate heat treatment in vacuo is usually unnecessary as tantalum does not work harden. After 95 % deformation, a tantalum product has typical hardness 180 HV, after an initial ingot hardness of 80 – 90 HV [46,47].

As well as its use for electrolytic capacitors (wire, cans, foil), semifinished tantalum is also

used in the chemical industry because of its excellent resistance to corrosion by hot, concentrated mineral acids, with the exception of hydrofluoric acid which strongly attacks tantalum. The passivation of the metal is a result of the dense, adherent oxide film, 1 – 4 nm thick, which forms spontaneously in air and in acidic media, and which is stable up to ca. 260 °C [48]. Welding of tantalum sheet is mainly carried out by the tungsten – inert gas (TIG) process, which allows complex heat exchangers and intricate heating equipment to be fabricated [49]. Impurity levels in commercial semifinished tantalum products are listed in Table 3.

Table 3. Typical chemical composition of commercial tantalum semifinished products

	Powder metallurgy grade	Electron beam melted grade
Ta	$\geq$ 99.9 %	$\geq$ 99.98 %
Impurity content, ppm		
O	250	100
C	75	30
N	75	30
H	15	10

W	10	20
Mo	5	10
Fe	75	10
Cr	15	3
Ni	20	2
Na	10	1
K	10	1

Because of the high price of tantalum, large vessels and pipework are often merely clad with the metal. Plating of steel with tantalum can be carried out by the explosion method [50], or corrosion protection can be achieved by build-up welding of tantalum [51].

5.3. Tantalum Powder for Capacitors

Since the first report that tantalum could be used for electrolytic capacitors [52], the growth of this application has been such that it now accounts for the highest consumption of the metal [53]. The capacitor consists of an anode of tantalum metal powder compressed into a pellet, typically 20 – 200 mg. This anode is sintered to give electrical continuity and density of ca. 6 – 9 g/cm^3. The electrical connection is provided by a tantalum wire, attached by sintering or welding. The whole of the pore surface of the sintered anode is coated with an amorphous dielectric layer of Ta_2O_5 by anodic oxidation, using an electrolyte of dilute H_3PO_4/H_2SO_4, sometimes with the addition of organic compounds [54, 55]. Ta_2O_5 has a resistivity of ca. $10^{15}\ \Omega \cdot$ cm [56] and dielectric constant $\varepsilon = 25$. The anode is coated with a semiconducting layer of MnO_2 by impregnation with an aqueous solution of manganese nitrate, followed by pyrolysis. This solid electrolyte provides the cathodic contact. Research has been carried out into the effect of the pyrolysis temperature on the Ta_2O_5 layer [57] and its dielectric properties [58], and also into the effect of temperature on the capacity [59] and conductivity [60–62], and the effect of these on the leakage current of the capacitor [63]. Progressive improvements to powder quality [64] have doubled the specific capacitance of the tantalum metal powder (the product of capacitance and formation voltage per unit mass) [65]. Typical qualities and properties of capacitor grade tantalum powder are given in Table 4.

5.4. Other Uses

Tantalum is used in medicine because of its lack of toxicity and very good compatibility with tissue. Reports and discussions have been published on the suitability of inhaled tantalum powder as a contrast medium in X-ray diagnostics of the throat, trachea, larynx, bronchi, esophagus, and stomach [66–68], but the material has been rarely used, mainly for cost reasons. Small tantalum spheres or tantalum wires are used in organs (e.g., the heart), in bone, or in implants as markers when controlling position and function by X-rays [69–71].

Because of its stable oxide layer, tantalum in the body is completely bioinert. It has been shown in animal experiments that, if broken bones are held in position with tantalum rods, even in septic conditions with corrosive tissue reaction, healing is better than when chromium – nickel steel or niobium are used [72]. Tantalum implants in the jaw have shown good metal – bone contact over many years with no morbid reaction [73]. Tantalum has been largely replaced as a prosthetic implant material by titanium, as this has better strength properties and is sufficiently bioinert [74]. However, tantalum has an important use in clips for rapid occlusion of ves-

Table 4. Typical properties of capacitor-grade tantalum powder

sels in surgery, either temporary or permanent, [75–77]. In some cases, tantalum mesh and plate can be implanted in damaged areas of the skull [78–80].

The possible use of the very dense and ductile tantalum for the manufacture of heavy missiles for armour penetration is under investigation [81].

6. Tantalum Alloys

Tantalum-Based Alloys. The most common tantalum alloy is Ta – 2.5 W, produced by ingot melting. This has higher strength and resistance to deformation than pure tantalum, but still has good cold working and welding properties. It is used for the construction of industrial chemical equipment, especially heat exchangers, pipes, and vessels. Its resistance to hot mineral acids (except hydrofluoric acid) is even somewhat greater than that of pure tantalum [82]. The alloy Ta – 7.5 W, produced by powder metallurgy, is harder, and is therefore a preferred material for springs in chemical equipment, e.g., valves. The alloy Ta – 10 W, mainly produced by ingot melting, is relatively hard, but still ductile. This, too, is used for special applications in chemical equipment, and in aircraft construction [82, 83]. For cost reasons, tantalum – niobium alloys have been proposed for chemical plant, but these alloys, Ta – 40 Nb [83] and Nb – 25 Ta [84], are less resistant to corrosion by hot acids.

The alloys Ta – 8 W – 2 Hf (T-111) and Ta – 9.6 W – 2.4 Hf – 0.01 C (T-222), which have good machining and high-temperature properties, were developed for use in air- and spacecraft, e.g., in nozzles, and for cladding the interior of combustion chambers and the exterior of rockets [85].

Earlier research led to the development of many other binary and ternary alloys of tantalum with Nb, W, Mo, Hf, and V [86, 87], Hf, W, and Al [88], or Ti and Al [89]. Some of these alloys have improved high-temperature properties and oxidation resistance compared with pure tantalum, but have not achieved industrial importance.

Superalloys. In superalloys, tantalum contributes mainly to properties such as high-temperature strength, reduction in fatigue at high temperature, and reduction of corrosion by sea air. Superalloys (→ High-Temperature Materials, Chap. 7.3.) are metallic multicomponent materials, with nickel, cobalt, or iron as the main constituent, and additions of tantalum, aluminum, chromium, hafnium, molybdenum, niobium, rhenium, titanium, tungsten, zirconium, etc., developed for use at high operating temperatures and under high mechanical stress. Components, produced by forging, casting, or powder metallurgy, are used in aircraft engines and stationary gas and steam turbines. These conventional superalloys contain up to 9 % tantalum (e.g., TRW-NASA VI A, MAR-M 302) [90]. The

manufacture of single- crystal components, e.g., for turbine blades, and the directional solidification of superalloys specially developed for this technique (e.g., Rene 142, with 6.5 % Ta and PWA 1480 with 12 % Ta) are processes of increasing importance [91, 92].

The effect of tantalum in the nickel-based superalloys B-1900 (4 % Ta) and MAR-M 247 (3 % Ta) has been systematically investigated. The favorable high-temperature properties are mainly due to the γ'-phase of the type $Ni_3(Al, Ti, Ta)$, formed by precipitation from the γ-phase. Tantalum increases the volume fraction of the γ'-phase in the γ'/γ ratio. For the most part, it appears in this phase without changing the partitioning ratios of the other elements. A small part of the tantalum appears in the metal carbide fraction, which improves the high-temperature strength [93, 94]. As well as the composition of the material or component, a multistage heat treatment is very important for optimization of γ'-phase precipitation.

7. Tantalum Compounds

Oxides. Tantalum oxides in lower oxidation states are not industrially important. Tantalum(II) oxide, TaO [*12035-90-4*], is the only lower oxide whose existence has been confirmed. It is produced from tantalum pentoxide by reduction with carbon at 1900 °C, or with hydrogen at 1100 °C. A possible use is for the production of heat-reflecting window glass [95].

No tantalum compound analogous to niobium(IV) oxide, NbO_2, is known. However, with tantalum pentoxide, the possibility exists of introducing interstitial tantalum atoms, so that TaO_x compounds can be obtained ($x = 2 - 2.5$). These oxides have metallic conductivity, but do not form discrete phases.

Tantalum pentoxide, Ta_2O_5 [*1314-61-0*] (M_r 441.9, *mp* 1880 °C, density 8.73 g/cm^3), occurs in two thermodynamically stable modifications, α and β. The transition temperature from the orthorhombic β modification to the tetragonal α modification is ca. 1360 °C. The existence of an ε modification, produced hydrothermally from tantalic acid at 300 – 340 °C, is also known. This ε-Ta_2O_5 is isomorphous with β-Nb_2O_5, and is transformed to β-Ta_2O_5 by heating in air above 886 °C [96].

Two processes are used for the manufacture of tantalum pentoxide:

Wet Chemical Method. The raw materials (ores and/or tin slag concentrates) are dissolved in hydrofluoric acid at ca. 100 °C. Tantalum and niobium are extracted from this strongly acid aqueous solution, preferably with methyl isobutyl ketone. The impurities that are also extracted, SiF_6^{2-}, FeF_6^{3-}, AlF_6^{3-}, SbF_6^{2-}, etc., are washed out with sulfuric acid, and the tantalum and niobium are separated in a multistage operation. Ammonia gas or solution is added to the aqueous H_2TaF_7 solution, forming hydrated tantalum oxide, $Ta_2O_5 \cdot n\,H_2O$ [*75397-94-3*]. This is washed, dried, and calcined above 800 °C to form the oxide (→ Niobium) [97].

Chloride Process. The ferroalloy produced by the pyrometallurgical method is chlorinated in an iron chloride – sodium chloride melt at 550 – 600 °C. The complex salt $NaFeCl_4$ present in the melt acts as a chlorine carrier. The iron loses a chlorine atom and is reduced from the trivalent to the divalent state, and the added chlorine gas causes the iron to be continuously reoxidized to Fe(III). The $TaCl_5/NbCl_5$ mixture is separated by fractional distillation to obtain the chlorides of the two elements in a highly pure state. To obtain the oxide, the ground chlorides are hydrolyzed with steam in a fluidized bed, and then calcined (→ Niobium).

In the optical industry, tantalum pentoxide is used in lanthanum borate glasses, characterized by their high refractive index and low optical scattering; since the 1980s, niobium pentoxide has been increasingly used for this application, as tantalum pentoxide is 3 – 5 times as expensive and has twice the density [98].

Tantalum pentoxide, and especially hydrated tantalum oxide $Ta_2O_5 \cdot n\,H_2O$ [*75397-94-3*], is used as an acid catalyst. In its amorphous form, its surface acidity can be as high as $H_0 \leq -8.2$ [99]. It therefore has good catalytic activity for alkylation, esterification, Beckmann rearrangement, aldol condensation, etc. [100–103].

Tantalates. Tantalates can be produced by calcination of oxide mixtures, or by dissolving tantalum pentoxide in molten alkali metal hydroxides or carbonates. Excess alkali metal hydroxides or carbonates leads to the formation of water-soluble tantalate isopolyanions $(H_xTa_6O_{19})^{(8-x)-}$, where $x = 0, 1$, or 2 [104].

The most industrially important tantalates are those of lithium and yttrium. Single crystals of lithium tantalate, $LiTaO_3$ [*12031-66-2*], are pulled from the melt crucible by the Czochralski method [105]. The crystal growth rate for crystals 5 – 8 cm in diameter is ca. 2 – 3 mm/h. These ferroelectric single crystals in the unpoled state have domains that are statistically distributed in the crystal. They are poled on passing through the Curie temperature (665 – 618 °C) in an electric field and then have only a single domain [106, 107]. Single- crystal wafers of $LiTaO_3$ are widely used as surface acoustic wave filters (SAW) for high-frequency applications in communication systems (intermediate-frequency filters in television and video equipment). Also, lithium tantalate is used in combination with lithium niobate in the manufacture of waveguides, frequency doublers (second harmonic generation), optical modulators, and optical switches.

Yttrium tantalate powder, $YTaO_4$ [*12143-49-6*], produced in a solid state reaction, is applied as an emulsion to a film, and is used in diagnostic medicine as a phosphor for the amplification of X-rays. It converts X-rays to fluorescent light in very high yield, enabling the X-ray dose received by the patient to be significantly reduced [108].

Barium magnesium tantalate, $Ba_3MgTa_2O_9$ [*12231-81-1*], and barium zinc tantalate, $Ba_3ZnTa_2O_9$ [*12231-88-8*], are likely to play an increasingly important role in the future as the base material for microwave resonators for the stabilization of oscillators, or as frequency filters. These dielectric materials, which have the perovskite structure, have high dielectric constant and very low dielectric loss at high frequencies [109–112]. These high-quality resonators are especially necessary for the high carrier frequencies in satellite communication.

Halides. Tantalum pentafluoride, TaF_5 [*7783-71-3*], (*mp* 96.8 °C, *bp* 229.5 °C) is produced by passing fluorine over metallic tantalum, or from tantalum chloride by adding anhydrous hydrogen fluoride [113–115]. Both tantalum pentafluoride and niobium pentafluoride are used in the petrochemical industry as isomerization and alkylation catalysts. The fluorides of both elements are also useful as fluorination catalysts for the manufacture of fluorochloro- and fluorinated hydrocarbons [116].

The oxyfluorides $TaOF_3$ [*20263-47-2*] and TaO_2F [*13597-27-8*] are also known, but have no industrial importance.

Potassium heptafluorotantalate (potassium tantalum fluoride), K_2TaF_7, is an industrially important intermediate in the production of tantalum metal (Section 5.1). It crystallizes in colorless, rhombic needles when K^+ ions (e.g., KCl or KF) are added to solutions of tantalum in hydrofluoric acid (e.g., H_2TaF_7 solution) from the extraction process. If the acidity is not high enough, undesired oxyfluorides are formed in addition to K_2TaF_7.

The solubility of potassium heptafluorotantalate in hydrofluoric acid solution decreases from 60 g/100 ml at the boiling point to < 0.5 g/100 ml at room temperature. As the corresponding stable niobium salt K_2NbOF_5 is significantly more soluble, tantalum can also be separated from niobium by fractional crystallization (Marignac process) [7].

Tantalum pentachloride, $TaCl_5$ [*7721-01-9*], *mp* 216 °C, *bp* 242 °C, forms colorless, strongly hygroscopic, needle-shaped crystals. On an industrial scale, production of this chloride is exclusively by chlorination of metallic tantalum, ferrotantalum, or tantalum metal scrap. This process is mainly used in the production of high-purity oxides [117, 118].

Tantalum pentachloride is soluble in absolute alcohol, with formation of the corresponding alkoxide [119, 121]. Ultrafine tantalum oxide powder can be produced by hydrolysis of this alkoxide [121].

Tantalum pentachloride and tantalum alkoxides are suitable for use in the chemical vapor deposition of tantalum metal or tantalum oxide.

The other pentahalides, $TaBr_5$ [*13451-11-1*] and TaI_5 [*14693-81-3*], are known, but are of no industrial importance.

Carbides. Tantalum carbide, TaC [*12070-06-3*], is golden-brown, *mp* 3985 °C (one of the highest known). It is added as powder in the manufacture of hard metals. Tantalum carbide can be produced by the direct carburization of Ta metal by carbon, or preferably by reaction of Ta_2O_5 with carbon at ca. 1900 °C. In hard metal mixtures based on tungsten carbide, tantalum carbide is present at concentrations

0.5 – 10 %. It improves the high-temperature fatigue strength and thermal shock resistance of the cutting tool. For details of its properties, production, and use → Carbides, Chap. 2.3.

Nitrides. Tantalum nitride, TaN [*12033-62-4*], is a hard material, like tantalum carbide, with good wear resistance. It is produced by heating tantalum in a pure nitrogen atmosphere at ca. 1100 °C. Tantalum nitride films are used as diffusion barriers in semiconductor technology [122, 123], and as protective coatings for moisture sensors [124]. Tantalum nitride is also sometimes found in small amounts (3 – 8 %) in cermets (base material Ti(C, N)).

Borides. The tantalum – boron phase diagram [125] shows the existence of Ta_2B [*12045-26-0*], Ta_3B_2 [*12228-67-0*], TaB [*12007-07-7*], Ta_3B_4 [*12045-92-0*], and TaB_2 [*12007-35-1*]. These hard materials are of little industrial importance. The borides may be produced by heating tantalum and boron in vacuo at ca. 1800 °C, or by electrolyzing a melt of Ta_2O_5, B_2O_3, CaO, and CaF_2 (→ Boron Carbide, Boron Nitride and Metal Borides, Chap. 3.).

Silicides. The silicides $TaSi_2$ [*12039-79-1*] and Ta_5Si_3 [*12067-56-0*] [126] are produced from the elements by heating in vacuo at 1000 – 1500 °C. Tantalum silicide targets were formerly used in the semiconductor industry for production of interconnections by sputtering [127], but tantalum silicides are no longer of any industrial importance.

8. Analysis

The analytical chemistry of tantalum is described in detail in several monographs [128–131]. Analysis for tantalum as a major or minor component or trace element in raw materials, ferroniobium – tantalum, scrap materials, and alloys must be distinguished from analysis for impurities in tantalum products. The classical method of analyzing for tantalum is by gravimetry after extraction as the fluoro complex on an ion-exchange resin [132]. Low concentrations, i.e., in the μg/g region, are usually determined photometrically [131].

When tantalum is a major or minor component in ores, scrap, etc., it is usually determined by fusion with sodium or lithium borate, followed by X-ray fluorescence analysis ($\geq$ 0.01 % Ta) [133]. Analysis of solutions by emission spectrometry with plasma excitation (ICP-AES) is increasingly used. Tantalum in the ng/ml region can be determined by measurement at 296.5 nm.

Because of the high purity required for electronic components, optical glasses, and superalloys, sensitive multielement methods have been developed for the determination of trace impurities in commercial products, e.g. potassium heptafluorotantalate, metallic tantalum, and tantalum oxide. The first methods were based on OES with vaporization in a carbon d.c. arc [134]. Additionally, many elements can be determined by plasma optical emission spectrometry (DCP-AES, ICP-AES) after dissolution by treatment with hydrofluoric or hydrofluoric/nitric acid under pressure [135]. Alkalis are determined by flame atomic absorption spectrometry, and arsenic, antimony, and other hydride formers by hydride techniques. Phosphorus, as a doping element in tantalum powders, can be very reliably determined photometrically [136]. Carbon and sulfur are determined by combustion analysis, and oxygen and nitrogen by hot extraction with a carrier gas.

Figure 2. Tantalum ore prices

As the optical spectrum of the tantalum matrix contains a very large number of lines, there are many possibilities for interference; trace ele-

Figure 3. Market share of tantalum applications, 1935 – 1993

ment – matrix separation offers the possibility to overcome the problems [135, 137, 138]. For the final determination, ICP-AES, ICP-mass spectrometry, or neutron activation analysis are used. For trace determination in the sub-ppm region, glow discharge mass spectrometry is now the most sensitive routine method of determination [139].

9. Economic Aspects

Figure 2 shows how the price of tantalum has fluctuated. The most important tantalum processors have made long-term ore contracts with the large mining concerns [140]. World production of tantalum ores (Table 1) is well below capacity.

World demand for tantalum has changed little since 1970, remaining at ca. 1000 t/a. Forecasts based on increasing tantalum demand for electrolytic capacitors [141] have not been borne-out, as developments in tantalum powders have meant that increasingly less tantalum powder is required for a given capacitor type [142]. However, the number of tantalum capacitors produced has grown continually, from ca. 2×10^9 in 1975 to ca. 9×10^9 in 1992 [53]. The most important area of use is for electrolytic capacitors, which account for >50 % of total world production of tantalum. The use of tantalum carbide as an additive in the hard metal industry, which was still important in 1980, has decreased in recent years [17] as TaC is being replaced by chromium and vanadium carbides for cost reasons. Figure 3 illustrates the shifting market shares of the various application areas over recent decades. Applications not included, e.g., Ta_2O_5 in optical applications and in X-ray phosphors, account for considerably less than 5 % of the market.

10. Toxicology

Metallic tantalum is completely nontoxic and bioinert, and allergic reactions are unknown. This has enabled it to be used in X-ray diagnostics and surgery (Section 5.4). Tantalum carbide is not known to have acute toxicity. Tantalum oxide is classified as nontoxic, although animal experiments indicate that the LD_{50} (rat, oral) is 8000 mg/kg (RTECS). For respirable dusts of metallic tantalum, the MAK value is 5 mg/m^3. Tantalum chloride has a strongly corrosive and irritant effect, owing to the hydrolytic production of hydrogen chloride. The LD_{50} (rat, oral) is 1900 mg/kg (RTECS). MAK values have not yet been established for tantalum oxide, tantalum carbide, and tantalum chloride. Potassium heptafluorotantalate has toxic properties due to its fluoride content; LD_{50} (rat, oral) is 2500 mg/kg (RTECS), and MAK for dusts is 2.5 mg/m^3 total dust (calculated as fluoride) [143].

1. Introduction

The first pressure sensitive adhesives were based on natural rubber and rosin. They were applied as patches and tapes for surgical use [1]. In the 19th century some early technical tapes were derived therefrom (e.g., Citoplast, P. Beiersdorf & Co., Germany), but the application range was very narrow. When spray painting was introduced in the automotive industry, such tapes were employed to mask color lines. They were imperfect and had to be improved [2]. This was the starting point for the development of industrial tapes.

Currently there are hundreds of varieties of pressure-sensitive tapes that differ in the adhesive base, the carrier material, and construction. They are used in practically all industries, in house and office, in hospitals and personal care.

Adhesive tapes generally consist of a flexible carrier or backing with a layer of a permanently tacky adhesive which sticks to most substrates by contact under pressure. There is no need for solvent or heat. The carrier often executes the function of the tape, e.g., to close a box, to protect or decorate a surface, to fill a gap, or to cover a wound.

The main types of adhesive tape are:

- *Pressure-sensitive tapes* consist of a carrier, coated, with adhesive on one side, and wound into a roll. The back side is often coated with a release agent to control the unwind force.
- *Double-sided tapes* generally consist of a carrier with adhesives on both sides and an intermediate release liner, to prevent contact of the adhesive layers when the tape is wound into a roll. There are also transfer tapes without carrier and tapes without release liner.
- *Adhesive pads* are pieces of thick layers of adhesives, or polymer foams with adhesive layers on both sides. They are often stretchable for ease of release from the surface.
- *Medical tapes* are composed of a backing coated with adhesive (porous, permeable or occlusive). Some have a wound pad.
- *Labelstock* consists of a writable or printable carrier coated with the adhesive on one side, which generally is covered by a release liner. This type is not treated here.

2. Pressure-Sensitive Adhesion

Normally adhesives are applied in a liquid state to the substrate, wet the surface, and solidify to generate a bond, for example by evaporation of a solvent, cooling of a hot melt, or formation of a cross-linked polymer. Pressure-sensitive adhesives do not change their physical state, but they also must wet the surface of the substrate like a liquid and sustain loads like a solid. There have been many discussions and investigations concerning how they fulfill these conflicting demands.

The first theories were based on the observation of two phases at the surface of rubber–resin adhesives. One, having high resin content, was assumed to act as sticky spots that adhere to the surface, while the other, with a low resin content, gave cohesion to the system [3,4]. But some contradictions remained unresolved [5].

Later investigations showed that combinations of rubbers with very effective tackifiers do not show the two-phase structure. Therefore, phase separation cannot be essential to pressure-sensitive adhesion. The above-mentioned conflict rather is resolved by the dependence of mechanical strength on the rate of deformation, that is, viscoelasticity. The tackifier resins decrease the modulus at the slow rate at which wetting occurs, and increase it at the higher rate at which the adhesion tests are carried out [6]. This is demonstrated in Figure 1, in which the mechanical strength is characterized by the storage modulus G' (the explanation is given later).

Figure 1. Effect of tackifier resin on the storage modulus of an elastomer [7]

To achieve a good compromise between wetting the surface (adhesion) and bearing a load (cohesion) the modulus should be in the range of 0.1 to 1 MPa "in the time frame of the bonding process", that is 1 – 100 s (Dahlquist criterion [9, p. 101]).

According to Williams – Landel – Ferry (WLF) principle longer time is equivalent to higher temperature. Thus at higher rates the modulus is shifted to the direction of lower temperature and vice versa [8].

2.1. Mechanism of Pressure-Sensitive Adhesion

Pressure-sensitive adhesion is a complex phenomenon determined by a number of physical processes. A comprehensive overview is given in [9].

Pressure-sensitive adhesion is determined by two key factors. First, the surface must be contacted to such a degree that molecular attraction forces come into action (wetting). The second factor is the energy of deformation of the viscoelastic adhesive until rupture or separation from the surface occurs.

The degree of wetting is controlled by thermodynamic and kinetic factors. The driving force for wetting a substrate is dependent on the surface energies of the adhesive and the substrate. The Zisman concept of critical surface tension provides the basis for estimating the surface energy of solids [10]. Typical values of critical surface tension (in mN/m) for polymer substrates follow [14]:

Polytetrafluorethylene	19.5
Poly(dimethylsiloxane)	22
Polypropylene	29
Polyethylene	34.5
Poly(methyl methacrylate)	41
Poly(vinyl chloride)	41
Polystyrene	42
Poly(ethylene terephthalate)	42.5
Polyamide 66	44

The influence of critical surface tension on peel adhesion, tack, and residues was investigated experimentally for rubber – resin [11,12] and polyacrylate [13] pressure-sensitive adhesives (PSAs).

The critical surface tension of a PSA cannot be determined directly, for when the test droplets of low polarity liquids are dissolved in the adhesive the contact angle is not defined. Therefore, this value was derived from those of chemi-

cally similar polymers, resulting in 33 mN/m for polyisobutylene and 35 – 36 mN/m for standard acrylic and rubber – rosin PSAs.

The study showed a maximum of peel force and residues on substrates having a somewhat higher surface tension than the adhesive. Hence, to have good adhesion, the adhesive should have low surface energy or the substrates should be treated to increase their critical surface tension.

Adhesion is enhanced further by contact time and contact pressure. Both increase the area of the wetted spots kinetically by flow of the adhesive. This is especially important for rough surfaces and cross-linked adhesives.

The role of the deformation energy can best be demonstrated by peeling a pressure-sensitive tape from a rigid substrate. During separation typically the adhesive becomes filamented and the "legs" are stretched to such degree that they break or separate from the surface. The former is a cohesive and the latter an adhesive failure. The energy required to achieve this is the peel force.

The correlation between peel adhesion and the viscoelastic properties of the adhesive is reviewed in [9, p. 61 ff]. A comprehensive experimental analysis can be found in [15]. The peel force is measured at various pulling rates and temperatures and superimposed on a master curve [8].

Figure 2. Master curve for the force of a tape peeled at 90 ° from a glass surface (transposed to 23 °C according to WFL principle [8])
○ Cohesive failure; ● Adhesive failure [PET film with adhesive (60 % rubber, 40 % β-pinene resin)] [15]

At low rates (i.e., at high temperatures) there is a region A of cohesive failure with a clear influence of pulling rate.

In region B at higher rate (i.e., lower temperature) the adhesive is still legging, but separation occurs at the surface. In this region the magnitude of the peel force is influenced by the area of molecular contact (i.e., by wetting). At still higher rates is region C, where the adhesive is pulled from the backing. Here the peeling force is dramaticly lower and independent of the pulling rate.

Between B and C is a transitional region, in which the peel force jumps from a higher to a lower level, so-called slip-stick. The upper limit is shown by the dashed line. It is believed that this is a periodical change from rubbery to glassy response during peeling.

Typically, pressure-sensitive tapes are applied in region B. The effective pulling rate of the standard peel test at 180° is 2.5×10^{-3} m/s, which is in the middle of region B (indicated by an arrow in Fig. 2). At very low temperature, region C may be reached. For application under freezer conditions, special tapes with lower T_g are available.

To avoid cohesive failure at higher temperature the adhesive can be cross-linked. This shifts region A to lower rates (i.e., higher temperature) or suppresses it entirely.

Viscoelastic properties are influenced essentially by the glass transition temperature T_g.

The optimal T_g is about 40 – 70 °C below the application temperature of the PSA. The T_g can be adjusted by means of the composition of the adhesive, especially by the concentration and the softening temperature of the resins.

The viscoelasticity and surface tension of adhesives are physical properties that are independent of the specific chemical composition. Therefore, the relations discussed for rubber-based adhesives are also valid for polyacrylates [16] and other elastomeric bases.

2.2. Dynamic Mechanical Analysis

The viscoelastic properties of a polymeric material can be described by its reversible and irreversible responses to deformation. These can be identified most easily by dynamic mechanical analysis (DMA). Usually, the adhesive is placed between two parallel plates, one of which is oscillating sinusoidally, and the torque is measured. From the amplitude and the phase shift

of the sinusoidal stress – strain curve, the elastic component, which is in phase, and the viscous component, which is 90° out of phase, can be derived [9, p. 158 ff].

Thus, the viscoelastic properties are characterized by the storage modulus G' (the elastic component of the modulus), the loss modulus G'' (the viscous component of the modulus), and $\tan\delta = G''/G'$ (the tangent of the phase shift between stress and strain), which are functions of the deformation rate and temperature. The method offers valuable information for the development and the application of adhesive tapes.

The maximum of $\tan\delta$ as a function of temperature is generally identified as the (dynamically defined) glass transition temperature T_g, which is dependent on the deformation rate. Usually it changes by 6 – 7 °C per decade of frequency [17, p. 253].

A mixture of two compatible polymers with different T_g values exhibits a single T_g which is influenced by the T_g values and weight fractions of the two components. In many cases this T_g can be calculated approximately by the Fox equation (Eq. 1) [17, p. 277 ff]

$$1/T_{g_m} = w_1/T_{g_1} + w_2/T_{g_2} \quad (1)$$

where T_{g_m}, T_{g_1}, T_{g_2} are the glass transition temperatures of the mixture and of components 1 and 2, and w_1, w_2 are the weight fractions of components 1 and 2.

A mixture of partially compatible polymers exhibits the T_g of at least one pure component and a T_g, which is dependent on the mixture, according to Equation (1).

3. Test Methods

Standard test methods are applied primarily for characterizing adhesive tapes and assuring product quality. To check whether a tape is suitable for a specific application generally requires more specific tests, which may be agreed with the customer.

Standard test methods for pressure-sensitive tapes are published by governmental and commercial organizations:

USA	Pressure Sensitive Tape Council (PSTC) [18]
USA	American Society for Testing Materials (ASTM) [19]
Europe	Association des Fabricants Europeens de Rubans Auto-adhesifs (A.F.E.R.A.) [20]
Europe	European Committee for Standardization (CEN) [21]

At present globally approved methods are being developed [22].

Adhesive properties of pressure-sensitive tapes are characterized primarily by three parameters: peel adhesion, shear adhesion and tack.

Peel adhesion is a highly characteristic property of a PSA. It gives the force per unit width required to remove a PSA tape by peeling from a test panel under defined separation speed and angle (0.3 m/min and generally 180° (Fig. 3), sometimes 90°). The backing can influence the results by its stiffness or stretchability. A more detailed discussion is given in [9, p. 61 ff].

Figure 3. Standard test methods for peel and shear adhesion of pressure-sensitive adhesive tapes

Shear Adhesion (Creep). The most significant example of creep is a tape gliding down under shearing load. Therefore, most commonly creep is characterized by the time a tape holds under defined shear load (Fig. 3). This often is called holding power or shear adhesion. Further examples of creep are the telescoping of rolls of stretchable pressure-sensitive tapes and the greasy spots occurring on a paper sheet mended by a transparent adhesive tape.

Resistance to long-term creep is critical for most applications of pressure sensitive products. According to WLF principle [8] long time is equivalent to high temperature.

The creep of a PSA can be minimized by increasing the molecular mass of the adhesive and by cross-linking it. But there are limitations, because some creep is necessary to wet the surface and to relax stress concentrations when the adhesive is stressed. This often is referred to as

the balance between adhesion and cohesion. The relevance of creep to PSAs is discussed in depth in [9, p. 97 ff].

To understand the reason for a failure caused by creep it is important to identify whether it is a cohesive failure (nearly the same amount of adhesive on both sides) or an adhesive failure (residue on one side only). In the first case, the adhesive is too soft or undercured, in the second it may be too hard or overcured. Furthermore, there may be a weak boundary layer on one surface. Sometimes there are structured patterns of adhesive on the surface. This is an indication of fracture as a result of stress concentrations [9, p. 115 ff].

Tack is the ability of a PSA to create a bond spontaneously under no or minimal external con-tact pressure. There are several aspects of tack, derived from different applications. Some consider the shortest time of contact, others the lowest contact pressure; some consider smooth, others rough surfaces.

The test methods can be classified into three groups (Fig. 4) [9, p. 38 ff]:

1) Rolling ball and rotating drum tests, in which the substrate runs on the surface of the adhesive. The measured quantity is the distance traveled or the imposed force, respectively.
2) Peel tests involving low contact pressure and short application time (e.g., the loop test).
3) Probe test, in which the tip of a probe is brought into contact under low pressure for a short time. The probe is withdrawn at a defined speed, and the butt tensile strength is measured.

Figure 4. Standard test methods for the tack of pressure-sensitive adhesive tapes
A) Rolling-ball tack; B) Rotating-drum tack; C) Loop-tack; D) Probe-tack

Shear adhesion failure temperature (SAFT) gives information on the resistance of the PSA to stress at elevated temperature. The geometry is identical to the shear adhesion test (Fig. 4). The test is performed in a forced-air oven with temperature rising at constant rate (0.4 °C/min). The SAFT is the temperature at which the bond fails and the load falls down. As this method is not standardized yet, there are some differences in overlap and load between companies [23, 24].

Further tests on adhesive and physical properties of tapes are:

- The unwind force of pressure-sensitive tapes
- The influence of aging on the unwind force of tapes
- Stains left on a substrate after removing the tape
- Strength and elongation of tapes under load
- Water and solvent resistance

For electrical tapes there are a number of very specific tests. More information is given in Chapter 6.

4. Raw Materials

The key component of PSA is the elastomer. It has the main impact on the physical and chemical properties of the adhesive. Its glass transition temperature can be raised either by adding sufficiently compatible resins or by copolymerization with suitable monomers. The composition of the adhesive also influences its surface energy, which is important for the ability to wet a surface.

4.1. Elastomers

Polydiene Rubbers. Most important of these is natural rubber (NR). Additionally used are butadiene – styrene rubbers (SBR) and synthetic polyisoprene rubbers (IR). They have very high molecular masses (several 10^5 to some 10^6 g/mol) and low T_g (– 70 to – 40 °C).

NR is classified internationally according to its production process, purity and Mooney viscosity [25, pp. 12 – 17]. From this, information

about the molecular mass of the adhesive can be derived, which is further influenced by the mastication and mixing process.

To achieve high tack and peel adhesion the T_g of the rubber must be raised by adding tackifier resins. The ratio of resins to rubber generally covers the range of 0.75 – 1.2.

Due to their main chain double bond, polydiene rubbers are prone to oxidative degradation and can be cross-linked by reactive resins and sulfur compounds [25, pp. 233 – 261]. Cross-linking can be achieved further by an electron beam (EB) and in presence of photoinitiators by UV radiation [26].

The adhesives are applied mainly from solvents, some are applied solventless by calendering or as water-based latices. More recently, solvent-free hot-melt processes have been introduced [27].

Styrenic block copolymers (→ Thermoplastic Elastomers, Chap. 5.) are special polydiene elastomers (polyisoprene or polybutadiene) of moderate molecular mass (7×10^4 to 2.5×10^5) with end blocks of polystyrene [(7 – 25) $\times 10^3$ g/mol]. They are thermoplastic elastomers: At low temperature the polystyrene blocks form spherical hard domains that act as cross-links in the adhesive and result in very high cohesion. Above about 90 °C they soften to give a melt of comparatively low viscosity like a thermoplastic [9, pp. 317 – 373].

There are different types of block copolymers: linear ABA, AB, and branched $(AB)_n$ with various ratios of A to B (A is polystyrene, and B is polybutadiene, polyisoprene, or their hydrogenated derivatives).

They must be compounded with resins to achieve high tack and peel adhesion. All ingredients must be selected carefully so as to independently control their influence on the elastomeric and the styrenic blocks [28].

Block copolymers with hydrogenated elastomer blocks are much more stable than those with unsaturated ones but they have somewhat limited adhesive properties. New developments will overcome this limitation [29].

After coating, the hot-melt adhesives can be cross-linked to compensate for softening at higher temperatures [30, 31].

Block copolymers are especially useful for hot melt and high-solids PSAs.

Acrylics. Polyacrylates (→ Polyacrylates) are copolymerized from different monomeric acrylates, optionally with some vinyl compounds. By selecting suitable comonomers, the T_g and the surface energy can be adjusted over a wide range. The most important monomers are listed in Table 1.

Table 1. Important monomers for acrylic PSAs

Monomer	T_g *, °C	Polarity
Soft monomers		
n-Butyl acrylate	− 54	low
2-Ethylhexyl acrylate	− 70	very low
Hard monomers		
Methylacrylate	+ 10	medium
Vinylacetate	+ 30	medium
tert-Butylacrylate	+ 43	low
Styrene	+ 100	low
Polar monomers		
Acrylic acid	+ 106	very high

* Quasistatic glass transition temperature of the homopolymer [37]

Further important parameters are the average molecular mass and its distribution, as well as the sequence of the monomers in the chain. These are set by the polymerization process.

Acrylic copolymers with suitably adjusted T_g are inherent pressure-sensitive adhesives, but they can be compounded with reasonably compatible resins to adjust tack, peel, and creep properties.

For most applications acrylic copolymers must be cross-linked. This can be performed by chemical reactions of the functional groups of the comonomers (amine with acid, epoxy with acid, diisocyanate with acid or hydroxyl, metal chelate with acid [32]) or by radicals generated by thermal decomposition of peroxides or by UV or electron beam (EB) radiation [33].

Most often acrylic adhesives are applied from solvent or as water-based emulsions. For special applications, like thick double-sided tapes, a solventless process has been developed in which a partially prepolymerized mixture of acrylic monomers is coated onto a liner and subsequently polymerized by UV radiation to form the adhesive [34]. Moreover, acrylic hot-melt adhesives cross-linkable by UV and EB radiation are being developed [35, 36].

Polyisobutylene and Butyl Rubber. Polyisobutylenes (→ Polyolefins, Chap. 4.) are

polymers of low polarity and low T_g and are available in a wide range of molecular masses. For pressure-sensitive adhesives, polymers with a viscosity average molecular mass M_v of at least 10^6 are used in combination with low molecular mass types.

Butyl rubbers are copolymers of isobutylene with minor amounts of a diene that enable chemical cross-linking via unsaturated sites. The M_v is in the range of $(3-4) \times 10^5$. To improve the possibilities for cross-linking, it can be mixed with halobutyl rubber, which contains the halogen in the α-position to the double bond.

Polyisobutylene rubbers can be compounded with resins to raise the T_g and hence peel adhesion.

Ethylene – Vinyl Acetate Copolymers (EVAc). The majority of EVAc is used for hard tack-free hot-melt adhesives. Pressure-sensitive properties can be achieved with types containing 40 – 60 % vinyl acetate compounded with compatible resins. EVAc-based PSAs are used only for specialty tapes.

Silicone Elastomers. The main component of pressure-sensitive silicone adhesives is a silicone elastomer with a molecular mass of several 10^5 g/mol. There are two types: One is neat poly(dimethylsiloxane) having very low T_g (− 125 °C) [38] and critical surface tension. The other is modified by substitution of 5 – 15 % of the methyl groups by phenyl groups. This results in higher T_g (ca. − 86 °C), higher surface tension, and improved heat stability [39].

High peel adhesion is achieved by compounding with silicone resins. Since they are only partly compatible, this mixture must be stabilized by reaction of some free silanol groups in both components.

To increase cohesion, silicone elastomers can easily be cross-linked via radicals generated by thermal decomposition of peroxides or by electron beam radiation.

Silicone elastomer based adhesives cover wide range of service temperatures (− 70 to ca. 250 °C) and provide excellent aging resistance. Owing to their low surface energy, they are the only adhesives applicable to low-energy substrates like silicone release liners and PTFE.

Normally, the adhesives are applied from aromatic solvents. Newer developments use the noble metal catalyzed addition reaction of Si–H to $H_2C{=}CH-$ for high-solids and solventless silicone PSAs.

4.2. Tackifier Resins

Tackifier resins are generally brittle amorphous materials with high softening temperatures (typically 40 – 150 °C) [40,41] and low molecular masses (some 10^2 to some 10^3 g/mol). Some are liquids that soften below ambient temperature. All should exhibit reasonable compatibility with the elastomer, which can be detected by the clearness of the mixtures or by dynamic mechanical analysis (see Chap. 2). Compatibility can be predicted from the cloud point temperature in suitable mixtures of solvents [42].

The presence of high molecular mass fractions, which often impairs the solubility of a resin, can best be recognized by the Z-average molecular mass M_Z.

The resins have important impact on the aging resistance of the adhesives. Unsaturated sites are susceptible to peroxidation. Most resins reduce the efficiency of radical cross-linking considerably.

Usually the resins are delivered as solids in barrels, as broken pieces, or as pellets or flakes. An increasing number are also available dispersed in water for water-based adhesives, and molten in tank trucks for hot-melt adhesives.

Rosin and Rosin Derivatives. The main component of rosins are rosin acids with two double bonds the molecule. They can be stabilized by hydrogenation or disproportionation. The softening temperature can be varied over a wide range by esterification, from the methyl ester (liquid) to the pentaerythritol ester (ca. 110 °C). Still higher temperatures are achieved by oligomerization. Rosin-based resins have a broad range of compatibilities.

Terpene resins (→ Resins, Synthetic, Chap. 2.) are produced by cationic polymerization of terpenes from turpentine or other sources. Poly(β-pinene) resins have the best compatibility to natural rubber. They are fairly stable, in spite of the double bond in the cyclohexyl ring. Due to increasing demands for terpenes and

decreasing availability, the resins are being substituted progressively by hydrocarbon resins.

Hydrocarbon resins (→ Resins, Synthetic, Chap. 2.) are produced mainly by cationic polymerization ($AlCl_3$ and BF_3) of carefully selected fractions from mineral oil processing. There are two main types: aliphatic resins from C_5 and $(C_5)_2$ fractions, and aromatic resins from C_9 fractions.

The aliphatic resins have good compatibility with natural rubbers and polyisobutylene. The degree of unsaturation, which has an impact on aging and radical cross-linking efficiency, is characterized by the bromine number. Recently an increasing number of aromatically modified C_5 resins with improved adhesive properties in natural rubber and block copolymers are available. Some are hydrogenated to improve aging properties.

Aromatic C_9 resins have good compatibility with SBR and EVAc elastomers, and some of them to acrylate copolymers. They have limited compatibility with natural rubber. For more details, see [9, pp. 527 – 544].

4.3. Plasticizers

Plasticizers (→ Plasticizers) are generally liquid substances of low molecular mass (some 10^2 to a few 10^4) that lower the T_g of the adhesive. Thus, they often reduce peel adhesion at ambient temperature but increase low-temperature adhesion. They increase tack and creep of the adhesive.

Most important groups are:

- Mineral oils, which may be aliphatic, naphthenic or aromatic
- Oligomers with low T_g, such as polybutenes, liquid resins, polyethers, and branched polyesters
- Long-chain alkyl esters of aromatic and aliphatic acids such as phthalic, adipic, sebacic, and trimellitic acids, which are typical PVC plasticizers

4.4. Fillers

Fillers are usually powdered inorganic solids. Primary parameters are the average and distribution of particle size, as well as the particle shape. For very small particles, often the surface area per unit weight is given instead of this. The key factor is the degree of dispersion in the adhesive, which is determined by the surface energies, the mixing or kneading process, and additives.

Fillers increase creep resistance and improve removability of the adhesives. If they are used as dyes, colorimetric parameters are important. For special purposes, fibers, spheres, conductive particles, etc. may be added to PSAs.

The most important groups of fillers are:

- Carbonates, silicates, and silica are the most common fillers. Interaction with the elastomers can be modified greatly by surface treatment with fatty acids or silanes. Pyrogenic silica has an extremely high surface area.
- Zinc oxide promotes chemical cross-linking by phenolic resins and thio compounds.
- Glass and polymer fibers are used to decrease strain under the influence of unwinding stress in unsupported double sided tapes (transfer tapes).
- Glass and polymer microspheres improve the stress distribution in the adhesive layer and the adhesion of thick double-sided tapes [43]. Organic microspheres containing low-boiling liquids can be used to foam an adhesive layer [44].
- Organic and inorganic pigments are used as coloring agents. Most common is titanium dioxide for whitening. Surface treatment can prevent light induced decomposition of the elastomer.

4.5. Stabilizers

In terms of stability the polydiene elastomers are the most critical due to their main-chain double bonds. Oxidative degradation is stimulated by elevated temperatures and the presence of unsaturated resins, typically used as tackifiers.

Elastomers with saturated chains like polyacrylates and polyisobutylenes are considerably more stable.

Primary antioxidants act by trapping radicals and preventing the initiation of oxidative chain reactions. Sterically hindered phenols are widely valued for their low- or nonstaining properties. Secondary stabilizers (e.g., phosphite esters and

special thioesters) decompose peroxides, which are responsible for autocatalytic effects.

Stabilization against UV can be achieved by UV absorbers such as derivatives of benzotriazoles and benzophenones, and by hindered amine light stabilizers (HALS). For more details, see [45].

4.6. Release Coatings

Release coatings are important components of pressure sensitive tapes as they enable the formulator to adjust the release force according to the application, for example, the unwinding force of tapes and the transfer of double-sided tapes to substrates.

The surface energy of a release coating is much lower than that of the adhesive. Thus the degree of wetting and adhesion are reduced. Further factors are the viscoelastic properties of the adhesive, the surface texture, and the number of pores in the release coat. External factors such as contact pressure, contact time and temperature should have as low an influence as possible.

There are three main types of release coatings:

- Release coatings based on long-chain alkyl groups yield medium release forces (0.1 – 1 N/cm). They are primarily used for the backsize of tapes. Examples are polyvinyl – stearyl – carbamate, chromium complex of C_{14} – C_{18} fatty acids [46], and stearyl copolymers [47].
- Acrylic polymers with perfluorated alkyl groups [48] are applied from solvent or as latex [49]. Their use seems to be rather restricted.
- The most common release coatings are silicones. They are based on poly(dimethylsiloxane), yield low to medium release forces (0.01 – 0.3 N/cm), and are applied primarily on release liners.

The key process for silicones is cross-linking, since residues of low molecular mass silicone oil on the surface of the PSA will eliminate tack.

The first reactions used were tin-catalyzed condensation reactions, which could be applied from solvents only. Since ca. 1980, noble metal catalyzed addition reactions have been introduced to coating technology. The combination with retarders gives systems which cross-link efficiently at high temperature (e.g., 10 s at 150 °C) but are fairly stable at ambient temperature. They can be applied without solvents. For more details, see [9, p. 601 – 626].

The influence of high temperatures can be avoided by radiation curing (UV and EB). There are two different processes: one is initiated by radicals [25, p. 355 ff] and the other one by ionic species [52]. Both processes allow the release force to be adjusted by means of additives to achieve controlled release.

5. Manufacturing Processes

Adhesive tapes generally consist of flexible backings with layers of primer, adhesive, and release coatings. Thus, manufacturing adhesive tapes essentially comprises compounding, coating and slitting processes.

The thickness of the layers and the viscosity of the coating materials vary over a broad range. Typical values are listed in Table 2.

Table 2. Thickness and viscosity of adhesive tape coating layers

	Thickness, µm	Viscosity, ∗∗ Pa · s
PSA	10 to 150 ∗	0.5 – 100
Primer	0.5 to 5	0.01 – 1
Release layer, backsize	0.1 to 2	0.001 to 5

∗ For special double-sided tapes, up to 2 mm. ∗∗ Upper values for 100 % systems.

The tolerance in thickness often has to be kept below ± 10 %. Typical line speeds are in the range of 50 to several 100 m/min.

In the beginning of the PSA industry, most compounding and coating was effected in solution. This still is the most versatile process. With increasing demands for environmental protection, solvent recovery and incineration have become widespread. They are rather effective, but require high investment and increased energy costs. Therefore, they are being substituted increasingly by solventless processes.

Coating of fluids such as primers and release agents are well described in the literature. A guide to selection is given by Cohen [53, p. 13 ff]. Important parameters are the required thickness and precision of the layer as well as the desired line speed, the properties of the coating

Table 3. Alternative manufacturing processes for PSA coatings

Process type	Fluidization by	Solidification by	Strong points	Critical points
Solvent-based	solvation	evaporation	most versatile adhesive properties full range of thickness	high cost for energy and equipment residual solvent, especially at higher thickness influence on some backings
Waterborne dispersions	dispersion in water	evaporation and coagulation	thin to medium thickness high cohesion applicable to solvent-sensitive films	low tack on plastics and rough substrates low water resistance electrochemical corrosion
Hot melt	heating	cooling	medium to very high thickness high peel adhesion high cohesion at ambient temperature high speed	low cohesion at higher temperature, (can be overcome by cross-linking) thermal and oxidative degradation
Reactive systems	(liquid components)	curing (chemical or radiation initiated reactions)	thin to very high thickness high cohesion good reversibility	low tack on rough substrates

Table 4. Alternative equipment for different manufacturing processes

Solvent-based	Waterborne	Hot melt	Reactive system
Compounding			
granulator + kneader (solid rubbers)	mixer	kneader (discontinuous)	mixer
mixer (soluble elastomers)		mixer extruder (continuous)	
Coater			
knife over roll	Meyer bar	slot die	reverse roll
reverse roll	air brush	melt roll	slot die
slot die	reverse roll	extrusion roll	
	slot die	calender	
Drying			
dryers + solvent recovery or incineration	dryer (air cleaning often necessary)	none	none
Cross-linking/curing			
high temperature	high temperature	radiation	mixing two components
radiation	radiation		radiation

(e.g., viscosity, solvent content, shear tolerance) and of the substrate (e.g., tolerance of thickness, roughness, absorbency).

Pressure-sensitive adhesives are compounded and coated in the fluid state and used in the solid state. Key characteristics of the process are the fluidization and solidification procedures. Four alternative types of process can be applied (Table 3).

These divergent processes require very different types of equipment. The most important are summarized in Table 4. A comprehensive treatment is given in [9, pp. 355 ff].

5.1. Compounding

Bales of natural rubber can be processed in two ways [33]:

1) With low degradation: Granulating the bales and kneading them together with all other ingredients in solution kneaders with sigma blades. If high-molecular rubber types like SMR-L (Standard Malaysian Rubber, light), ADR (Air Dried Rubber), or crepe are used, the resulting PSAs can be applied for general

purpose tapes without cross-linking. Primary disadvantages are slow batch processing and low solids content or high viscosity of the coating materials.

2) With high degradation: The rubber bales are milled down together with the filler in an internal mixer with intermeshing blades within a few minutes. Subsequently this mill base is dissolved and compounded with tackifiers and further ingredients in a solution mixer. Process time is much shorter, but cross-linking is indispensable even for tapes with standard performance.

Compounding block copolymer based hot-melt adhesives can be performed batchwise in heated kneaders or continuously in mixing extruders [54, 55]. A survey of the designs and parameters of suitable extruders is given in [56].

Compounding of soluble elastomers, dispersions, and liquid components is described in detail in [53, pp. 23 – 61].

5.2. Coating

Standard equipment for solution based PSAs are knife over roll and reverse roll coaters (Fig. 5) [53, p. 13 ff]. For high-speed application, a closed reservoir or a slot die is preferred for better control of air bubbles [58]. Especially the knife over roll coater allows for an easy change of the coating material.

Figure 5. Standard coating equipment for PSAs
A) Knife over roll; B) Reverse roll coater

The coating can be applied directly to the web or to a release liner and subsequently transferred to the web. The latter method is often used for double-sided tapes with foam backings, for it eliminates the influence of solvent and high temperature on the substrate.

For hot melts, roll coaters and die systems are used (Fig. 6). Typical coating temperatures are in the range of 120 – 160 °C.

Figure 6. Coating equipment for pressure-sensitive hot-melt adhesives
A) Roll coater; B) Slot die coater; C) Extrusion die coater; a) Chill roll; b) Rotating rod

Roll coaters are largely free from interference caused by particles and variations in web thickness. The coating material can be changed quite easily. However, the influence of oxygen on the adhesive cannot be excluded completely, resulting in higher degradation of polydiene block copolymer hot-melt adhesives.

There are two types of coating dies: In the *slot die* coaters the coating is pressed onto the substrate. The thickness of the layer is controlled by the gap between the die lips and the web, which is backed by a steel or hard rubber roller. At the forward lip there may be a rotating rod to reduce stripes caused by particles. The pressure improves the contact of the adhesive to the substrate. The thickness of the coating is influenced by the web thickness. Further details are given in [59].

In the *extrusion die* coater, the coating layer is formed and calibrated in the slot and laid down on the substrate. The thickness is independent of the web thickness and can be reduced by stretching. There is no penetration through open substrates like fabrics, and there is no influence of particles on the coating. Good contact to the substrates can be provided by an air knife or a suction slit.

5.3. Drying

In solvent- and water-based systems the drying process is often the limiting factor for the line speed. Thus, it determines the economical efficiency of the production line and has to be considered carefully for all products.

Up to coating weights of about 50 g/m^2, forced air drying tunnels (Fig. 7 A) are employed. The air is pressed through holes, slots, or nozzles onto the web. Usually the dryers are segmented to cope with the different drying regimes

[53, pp. 267 – 298]. In single-side dryers, the web is backed by rolls or by a belt. Most efficient are two-sided floater dryers, in which the web hovers between specially designed air nozzles on both sides.

For higher coating weights, festoon dryers (Fig. 7 B) can be used. In this type of dryer, long loops of the web hanging on rods are moved slowly through a sealed room, which may have a volume of more than 500 m^3. The air is pressed through nozzles from the ceiling into the loops. Further details are given in [53, pp. 86 – 91].

Figure 7. Drying equipment for pressure-sensitive adhesive tapes
A) Drying tunnel; B) Festoon dryer

In all air dryers, the concentration of the solvents must be kept below 50 % of the lower explosion limit (e.g., ca. 20 g/m^3 for hexane and toluene, ca. 40 g/m^3 for ethyl acetate [60]). In high-performance lines huge amounts of air have to be heated, transported and finally purified of solvent, for example, by adsorption processes.

An alternative method is incineration. As the solvent concentration is low, effective heat recovery equipment is necessary to reduce the amount of additional fuel [53, pp. 110 – 115]. Catalytic oxidation often is inhibited by widely used substances like silicones and amines.

Energy consumption can be reduced if oxygen is excluded from the dryers. This can be achieved by substituting the air by nitrogen in a closed loop. In this case the solvent concentration can be greatly increased, so that the flowing gas volumes are reduced considerably and the solvent can be condensed at about – 5 °C. The disadvantages of this method are the limited accessibility of the coaters and drying tunnels and the need to seal the inlet and outlet of the web sufficiently.

5.4. Cross-linking / Curing

Cross-linking can be effected by chemical reactions of reactive groups in the elastomer among one another or with reactive additives. The reaction must not start until after the coating process. This is effected by high temperature, which may be achieved in the last sections of the drying tunnel or in a separate high-temperature tunnel.

Radiation curing is very appropriate to cure PSAs, as the transferred energy is far higher than in thermal cross-linking. Both electron beam (EB) and ultraviolet (UV) radiation are applied. Their physical characteristics differ, as shown in Table 5 [61].

Table 5. Characteristics of EB and UV radiation

	EB radiation	UV radiation
Particle/quantum energy	150 – 300 keV	3 – 6 eV
Generation of radicals	stochastically by all matter	by the photoinitiator (PI) only
Absorption of the radiation	by all matter	by specific components
Penetration depth	dependent on density and particle energy	dependent on wavelength and concentration of components, especially the PI

These differences result in different kinetics. The energy of EB radiation is several tens of thousands times higher than the energy of chemical bonds. A primary electron transfers its energy in a cascade of secondary and tertiary electrons to several thousand molecules, generating reactive sites stochastically in the elastomers, the resins, and all other additives. The radical sites on the elastomers result in cross-linking of the adhesive. In the presence of reactive monomers, there is a high degree of grafting.

The quantum energy of UV radiation is comparable to chemical bond energies. The radiation is absorbed by the photoinitiator, which is converted to free radicals or to a highly reactive state. These sites generate cross-links at the elastomers; in the presence of monomers, they can initiate polymer chains.

The other difference concerns penetration depth. As EB radiation is attenuated by all matter, penetration depth is a function of electron energy and density, e.g., at 300 kV the useful penetration depth at a density of 1 g/cm^3 is 0.35 mm

[62]. In a clear layer of nonabsorbent polymers the penetration depth of UV radiation may increase with the absorbed irradiation energy (i.e., irradiation time) [63]. With low concentration of the photoinitiation, optimal wavelength, and sufficient irradiation time, coatings with a thickness of more than 1 mm can be cured.

Details about equipment and process parameters are given in [64,65].

5.5. Slitting, Cutting

For high efficiency, coating usually is performed over a width of more than a meter. The tape rolls are obtained by cutting the web into strips with a width of a few millimeters up to several centimeters. Four methods are applied (Fig. 8).

Figure 8. Slitting methods for pressure-sensitive adhesive tapes
A) Shear cutting; B) Crush cutting; C) Log cutting; D) Razor blade cutting
a) Web; b) Log

Shear cutting (Fig. 8 A) is effected between a rotating knife and a roller edge and results in tapes with smoothly cut edges. This method has the highest precision, but the width of the tape rolls cannot readily be changed. It is used for most rigid-film tapes and double-sided tapes.

Crush cutting (Fig. 8 B) is effected by pressing a rotating knife against a steel roller. The edges of the tapes are roughened by small cracks. The precision is lower than that of shear cutting, but the width can be changed more easily. This method is usually applied for paper-, fabric-, and nonwowen backed tapes. In a special case biaxially oriented polypropylene (BOPP) based films are cut by such a process to achieve hand-tearable tapes.

In log cutting (Fig. 8 C) the coated web is wound into rolls or logs in full width and in the desired length of the tape rolls. Subsequently, these logs are sliced by a rotating knife, which is moved transversally between slices to match the width of the tape rolls. As the transverse location can be adjusted deliberately by a computer, this process allows the complete customization of the width of the tape rolls.

In razor blade cutting (Fig. 8 D) the web is cut by parallel razor blades. The edges are cut very smoothly. Due to the lower stiffness of the blades the precision is lower than with the other methods. It is preferred for, e.g., carton-sealing tapes.

6. Adhesive Tape Products

Hundreds of divergent pressure-sensitive adhesive products are available to cope with numerous applications in industry, office, household, etc. They differ in material and/or in design. Most are wound into rolls; some are die-cut into separate pieces or assembled on sheets.

A detailed presentation of all the products and applications is beyond the scope of this article. Reference is made to the *Handbook of Pressure Sensitive Technology* [9].

6.1. One-Sided Adhesive Tapes

Generally such tapes are composed of four layers:

1) Pressure-sensitive adhesive
2) Primer
3) Backing (carrier)
4) Backsize (release coating)

The backsize and the primer are optional components. The former is used to adjust the unwinding characteristics and/or to seal a porous backing material. The latter provides for good bonding between adhesive and backing. In many cases, instead of using a primer the film surface is treated by corona discharge or with a flame. Sometimes the primer also contains an agent which cross-links the adhesive by diffusion into this layer.

6.1.1. Film Tapes

Film tapes have by far the largest production volume. According to the deformation properties there are two kinds of film tapes.

Rigid Film Tapes. *Cellophane* is the oldest transparent tape backing. It is fairly strong and transparent and is widely used to fasten package wrappings, to seal cartons, and for a great variety of other sealing, holding, and mending jobs. However it is not resistant to moisture and has become rather expensive due to environmental protection regulations in the production process.

Cellulose acetate film is resistant to moisture but lacks the toughness of cellophane. In combination with an age-resistant acrylic adhesive and a matte backside it is used in many countries for office tapes to repair torn books, etc.

Considerable amounts of oriented *poly(vinyl chloride)* (PVC) films are used for tapes in Europe. In combination with solvent-based rubber–resin adhesives, they yield high-performance packaging tapes with smooth unwind characteristic without the need for a backsize. *Biaxially oriented polypropylene* (BOPP) tapes with hot-melt adhesives based on styrenic block copolymers have now attained the biggest share of the market for carton-sealing tapes. They require a backsize, and on unwinding they evolve much noise.

By using waterborne acrylic dispersions, UV-resistant packaging tapes with quiet unwinding are produced. Most of them are used as carton-sealing tapes. Further applications are protection of labels and documents.

By stretching PP films predominantly in the machine direction, the tensile strength in this direction can be increased further at the expense of strength in transverse direction. Such tapes are referred to as machine direction oriented polypropylene (MOPP) and tensilized polypropylene (TPP) films and are used for strapping and bundling heavy goods, to secure pallets, and to tear the corrugated cardboard to open boxes. These tapes often are wound into special rolls with lengths of up to 70 000 m by cross-spool winding.

For more information on packaging tapes, see [9, 66].

The upper temperature limit of a film tape is given by the softening of its backing, which may be caused by the glass transition (e.g., PS, PVC films) or by the melting of crystalline regions (e.g., PE, PP, PETP films). The low temperature limit is given by embrittlement of the film, or more often by the glass transition of the adhesive, which is not considered here.

To assess roughly the temperature range of the most important film backings some values are given in Table 6, valid for adhering films at low stress. It should be noted, that for long-term service, the upper limit may be reduced considerably due to degradation processes and interaction with the adhesive. This is treated in more detail in Section 6.1.6.

Table 6. Application temperature range (short-term) of important film backings [67, 68]

Film	Application range, [a], °C	
	min.	max.
Cellophane	0	150
Low-density Polyethylene [b]	− 50	95
High-density Polyethylene [b]	− 40	80
Oriented Polypropylene	0	100
Rigid PVC	− 15	75
Plasticized PVC [b]	− 30	100
Poly(ethylene terephthalate) [c]	< − 100	160
Poly(ethylene naphthenate) [c]		200
Poly(ether ketone)		240
Polyimide	< − 100	350

[a] Temperature range over "which no significant loss in strength or stiffness occurs" [67]. [b] Conformable films. [c] Biaxially oriented.

A comprehensive survey on further film properties is given in [67].

Producers and Trade Names: Asia Chemical Corp., Beiersdorf (tesa tapes), Intertape Polymer Group, 3M (Scotch tapes), Scapa Tapes Klebetechnik (Cellux, Sellotape), Vibac.

Conformable Film Tapes. For many applications the tape should conform to a rugged or profiled surface. There are two types of films, which differ in their tensile stress elongation curve.

Type A tapes are made of semicrystalline polymers like PE. On extending such polymers beyond the yield point, the film deforms irreversibly at nearly constant stress until it finally increases to the breaking point. Type B tapes are made of amorphous plastics like plasticized PVC or rubbery EPM copolymers. Here the stress increases steadily up to the breaking point. It is a rubberlike reversible deformation. There

is always a residual stress in the adhesive bond. Therefore the adhesive needs sufficient cohesion. Typical values are shown in Fig. 9.

Figure 9. Deformation characteristics of conformable films

Tapes of type B are used for insulating and bundling wires and for cable harnessing. Plasticized PVC usually contains low molecular mass plasticizers, which may migrate into the substrates and adhesive. This can cause swelling of the substrate, and the tape may become brittle due to loss of the plasticizer.

Conformable films of type A are used as film-masking tapes and as thick films for corrosion protection tapes for underground transmission pipes.

Producers and Trade Names: Beiersdorf (tesa tapes), Coroplast Fritz Müller KG, 3M (Scotch tapes), Nitto Denko Corp., Raychem, The Tapecoat Company.

6.1.2. Fiber-Reinforced Tapes

To increase the mechanical strength of a film tape further, filaments can be embedded into the PSA. Most common are glass fibers; alternatives are polyester and polyamides. Such tapes have high tensile strength and low elongation under stress. Further, they are highly resistant to tear propagation, which is a weak point of biaxially oriented films. These tapes are suitable for heavy-duty applications.

Producers and Trade Names: American Tape Company, 3M (Scotch tapes).

6.1.3. Paper Tapes

Paper is a widely used backing for pressure-sensitive adhesive tapes. It is more expensive than simple plastic films but has several advantages. It is easy to tear by hand, tear strength is sufficient for many applications, it does not soften at high temperatures, and it can be upgraded by coating or saturating with polymers.

Flat Kraft Paper Backing. Usually the back side of the kraft paper is coated with PE by extrusion and additionally with a silicone release layer. The other side is coated with the PSA. Tapes with regular kraft paper have low elongation at break (ca. 4 %). This can be increased to ca. 10 % by corrugating the paper using the Clupak technology. Kraft paper tapes are quite common in Japan for carton sealing and general purpose packaging.

Creped paper backings can be divided roughly into two groups.

Thick creped papers with a thickness of more than 300 µm can be used without a backsize coat for high-elongation masking tapes for painting.

Flat creped papers saturated with rubberlike polymer latices generally have a backsize coating to control the unwind characteristic without impairing the adhesion of paints. In combination with natural-rubber-based adhesives, these tapes are used for masking in the automotive industry, for assembling electronic components, and insulation of low-voltage devices etc.

For high-temperature paint curing, the adhesive is cross-linked and thermosetting, i.e., it contains reactive resins, which produce additional cross-links during application in the high-temperature drying tunnels.

Producers and Trade Names: American Tape Company, Beiersdorf (tesa tapes), 3M (Scotch tapes), Nitto Denko Corp., Permacel, Shuford Mills, Sicad.

6.1.4. Textile Tapes

Fabric-based PSA tapes combine low stiffness with high tensile strength and low elongation. Usually they are tearable by hand. The backside can be open, coated with an acrylic finish, or extrusion coated with PE copolymers. *Duct tapes* are produced by combining a rubber-based adhesive, a wide-mesh fabric, and a PE film by calendering in a one-step process. Fabric tapes

are used for a vast number of divergent applications.

For many applications *nonwovens* or *fleeces* are used. Such tapes may be coated with a porous or impervious backsize.

Producers and Trade Names: Beiersdorf (tesa tapes), 3M (Scotch tapes), Nichiban, Scapa Tapes Klebetechnik (Fermoflex, Rotunda).

6.1.5. Other Backings

Foams. Very common are polyurethane foams. Foams based on polyesters have better heat and light stability than polyethers but have inferior stability against moisture. To increase light stability, they may contain carbon black. The PU foams are increasingly being substituted by foams based on PE and PE copolymers. For very high temperatures, silicone-based foams are available. The main applications of foam tapes are sealing gaps and damping vibrations.

Producers and Trade Names: Illbruck Industrieprodukte, Norton Company, Rubber Astic, Venture Tape Corporation.

Metal Foils. Most common is aluminum, less common are copper and lead. Such tapes are quite conformable and are used to seal against moisture and water. Tapes with aluminum foils or aluminum-coated films can shield surfaces against thermal radiation. Copper and aluminum foils and vapor-coated films also can be used to shield against electromagnetic interference.

Producers and Trade Names: Coroplast Fritz Müller, 3M (Scotch tapes).

6.1.6. Electrical Tapes

Electrical tapes comprise different types of backings. Conveniently they are treated in a separate section as they have to fulfill common specific requirements e.g. good electrical properties under dry and moist conditions, long service life at elevated temperatures, and often they need flame resistance and must be free from any substance corrosive to metal surfaces and from any emission harmful to electrical contacts.

These requirements are described by national and international standards like PSTC [18], UL [69], ASTM [19], VDE [70], and DIN [71]. The International Electrotechnical Commission (IEC) [72] has established a worldwide network to unify all national standards and test methods concerning electrical tapes.

As temperature often is the dominant aging factor in electrical insulating systems, certain basic thermal classes have been recognized internationally (Table 7).

Table 7. Thermal classes for electrical tapes for long-term service life at elevated temperature

Thermal class	Temperature, °C	Typical backings
Y	90	stabilized PVC
A	105	saturated paper, cotton fabric, acetate film
E	120	
B	130	poly(ethylene terephthalate) film, fabric, nonwoven
F	155	poly(ethylene naphthenate)
H	180	polyimide, glass fabric

Within each class certain combinations of backings and adhesives are feasible. For long-term service above 150 °C, silicone-based PSAs must be used.

For more details see Bräunling [9, p. 643 ff] and Külper [73].

Producers and Trade Names: 3M (Scotch tapes), Nitto Denko Corporation, PPI.

6.2. Double-Sided Adhesive Tapes

Double-sided tapes usually are used to attach substrates to one another; therefore, the adhesive is of primary importance. Generally, the backing material, if present, must assist the handling.

In high-performance tapes the backing consists of a relatively thick highly compliant cross-linked polymer layer, which may be foamed, and has a major impact on the strength of the bond.

Generally a double-sided PSA tape comprises five layers together with a release liner consisting of three additional layers:

- Pressure-sensitive adhesive 1
- Primer 1
- Backing (carrier)
- Primer 2
- Pressure-sensitive adhesive 2
- Release coating 1
- Release liner

– Release coating 2

Primers are optional, and in case of polyolefins can be substituted by corona, flame, or fluorine treatment.

6.2.1. Standard Double-Sided Tapes

Most double-sided tapes have cross-linked acrylic PSAs, which often are tackified with compatible resins. The adhesives on both sides can be identical or different, for example, to combine reversible and permanent bonding. Some adhesives are based on natural rubber or styrenic block copolymers.

Widely used backings are rigid and conformable films, nonwovens, fabrics, creped paper, and foams based on polyurethanes, polyolefins and their copolymers, etc. Generally the thickness of the adhesive layer has to be increased with increasing roughness of the substrates. Foams are especially useful for rugged or profiled surfaces.

An important element is the interliner, which mainly is coated with a silicone release agent, as described in Chapter 4. Glassine kraft paper is used most frequently. Creped paper, rigid and semirigid films are also used. Besides the peel force, stiffness and conformability are significant features of the interliners. More detailed information is in [9, p. 691 – 705].

Double-sided tapes are used for a vast diversity of applications in industry and household. Further important applications are laminating narrow profiles and wide substrates like foams and thick mats to endow them with pressure-sensitive adhesion. Two special applications are:

1) In the papermaking and printing industry splicing tapes are used to bind the end of one roll of paper to the beginning of another. This must be effected at high speed, and the bond often has to bear high temperature. Moreover, as the tape has to be returned to the papermill for reprocessing, the adhesive and the backing have to be repulpable (i.e., soluble or dispersible in water). Such PSAs are based on highly acidic polyacrylates and compatible water-soluble plasticizers. The dispersibility is adjusted by partial neutralization with alkali [74].
2) Double-sided tapes are used further to fix the printplates onto the printing rollers. The adhesive has to ensure that the tape is mounted easily and the plate stays down during the printing process. After finishing the plate must be easily demountable without residues.
   Very important for the print quality is the type and hardness of the backing: Film backings are mainly used to print solid areas. Foam backings are used for half-tone and combination prints. The backing has to exhibit a high recovery rate to achieve high printing speed with constant quality.

Producers and Trade Names: Beiersdorf (tesa tapes), Lohmann (Duplocoll tapes), MACtac, 3M (Scotch tapes), Nitto Denko Corporation.

6.2.2. Transfer Tapes

In transfer tapes, the PSA is coated on the release liner without additional backing. Therefore the release forces on both sides of the liner have to be precisely different and constant over storage time. The adhesives sometimes contain short-cut glass fibers to decrease the elongation during unwinding. Such tapes are used to transfer the PSA to extruded profiles or other parts to endow them with pressure-sensitive adhesion. For use in household and office, special dispensers are available.

Producers and Trade Names: Avery-Dennison Corporation (Fas tapes), Beiersdorf (tesa tapes), MACtac, 3M (Scotch tapes), Scapa Tapes Klebetechnik (Cellux).

6.2.3. Adhesive Pads and Strips

Adhesive pads and strips are die-cut pieces of relatively thick layers of highly conformable but cohesive PSA covered with release liners on both sides. Often they have a backing or core of polymeric foam. They are used to fasten objects to many surfaces.

Adhesive strips are constructed so, that in spite of their high adhesion, they can be removed easily from all surfaces just by stretching them in the bond direction. This principle first was used for medical applications [75]. More recent developments allow objects weighing up to a few

kilograms reversibly to be fastened to various surfaces [76].

Producers and Trade Names: Beiersdorf (tesa Power Strips), 3M (Scotch Command Tack).

6.2.4. High-Performance Tapes

Peel strength and adhesion under bending load can be increased by combining a highly cohesive PSA with a tough conformably balanced viscoelastic backing of adapted thickness. Such tapes also give very high bond strength on rough or profiled surfaces. Adhesion can be promoted further by application of pressure and elevated temperature (30 – 50 °C) during the bonding process and by careful exclusion of air bubbles at the interface.

The first products were based on UV-cured acrylics with a thickness of 0.3 to a few millimeters filled with glass microbubbles [77]. This has been extended now to a range of products for various interior and exterior applications, e.g., in the construction, automotive, building, and electronic industries. Such performance can be achieved also by polyurethanes [78] and other elastomers.

The performance of PSAs has been upgraded further by introducing thermosetting acrylic adhesives. This is achieved by additional epoxy groups in the PSA, which are initiated by heating after application of the tape [79].

Producers and Trade Names: Lohmann (Duplocoll tapes), 3M (Scotch VHB tapes), Norton Company.

6.3. Medical Tapes

Medical tapes are the oldest application of pressure-sensitive tapes [1]. Major progress towards skin compatibility was made by introduction of zinc oxide into the rubber-based PSAs [80]. With the development of polyisoprene, polyisobutylene, and other synthetic elastomers, natural rubber was replaced to a certain extent in medical products by synthetic rubbers. These were followed by the styrenic block copolymers [9, pp. 317 – 373].

In the late 1950s, polyacrylate-based PSAs were developed [81] and gained a dominant market share in the following decades. To a smaller extent poly(vinyl ethers) are used in medical devices. For specific applications like transdermal drug delivery systems, ostomy mounts, and electrically conductive adhesives a variety of specialty polymers such as silicones, polyurethanes, and various hydrogels are applied.

Nevertheless, both rubber- and acrylate-based PSAs are still important for medical products. Rubber-based adhesives have high tack in combination with a medium cohesive strength. The advantage of acrylics is their low allergenicity and the possibility to polymerize tailor-made products for particular applications. This is achieved by the choice of type and ratio of monomers for the polymerization and cross-linking process.

Basic characteristics of PSAs for medical applications are: Fast wetting of the skin during initial adhesion, secure adhesion on various skin types during application, and complete and pain-free removability. For resistance to moisture such as water or sweat, good permeability to water vapor and air is required.

Pressure-sensitive adhesive products are utilized in a broad variety of medical applications in very different fields: First aid products for consumers, medical tapes, island dressings, surgical drapes, wound-closure strips in hospitals and physician's practices, as well as tapes and bandages for orthopedic and athletic use. Other uses include transdermal systems for therapeutic purposes, and ostomy mounts, attaching electrocardiogram devices, and protective foot products.

First-Aid Bandages. The most widespread medical PSA products are the small bandage strips. This bandage is composed of a backing material coated with an adhesive and a small absorbent wound pad [82]. The adhesive layer is covered by a release paper or plastic film which is removed before use. For this kind of products plastic films (e.g., polyolefin), rigid or elastic fabrics, and nonwovens are applied. To attain an appropriate permeability, in many cases the backing material is perforated.

Hospital Tapes. Many hospital products are used under sterile conditions. Therefore, the raw materials have to be resistant to different sterilization methods. For several medical devices, transparency to X-rays enables examination without removing the bandage.

Depending upon the nature of the backing material, it is possible to manufacture occlusive as well as vapor-permeable products. Permeability to water vapor results in a better skin adhesion because the accumulation of moisture between skin and adhesive is avoided [83].

Medical tapes are used for all kinds of fixing purposes. The carrier of medical tapes can be woven fabric, film, perforated film, laminates, and nonwovens.

Island dressings applied after surgery are designed to absorb wound fluid either in their wound pad or in especially designed adhesive systems like hydrogels and hydrocolloids. Others are made of translucent films to enable inspection of the wound without removal of the dressing.

Self-adhering surgical drapes assure a sterile environment for surgery by isolating the operative area from resident skin bacteria. Due to the very elastic and flexible properties of the films (e.g., polyolefin or polyurethane) and their thin adhesive layer, they conform tightly to even difficult anatomical contours.

Wound-closure strips cover the field of small incisions or injuries which easily can be closed without stitches. The strips are made from a rigid fabric coated with a highly biocompatible PSA.

Orthopedic Tapes. In orthopedic applications, PSA products are most frequently used as tapes and elastic adhesive bandages. The tapes consist of a rigid backing material (e.g., cotton fabric) coated with the PSA. They are used in therapeutic medical applications to control motions and to immobilize and to stabilize joints in athletic use. Orthopedic bandages are made from coated elastic material and often are used when compression and support are to be supplied to the extremities.

Transdermal Systems. The use of transdermal drug delivery systems in pharmaceuticals has also become an important area for PSAs. This noninvasive form of drug application allows for a controlled release of bioactive substances. On applying the patch to the skin, the release of the active ingredient starts immediately and stops upon removal. During application the PSA has not only to ensure the proper adhesion of the product but also the drug delivery into the skin. This may either be achieved from a reservoir through the adhesive (membrane system) or from an adhesive that itself contains the drug (matrix system). In transdermal drug delivery systems [84] highly biocompatible adhesives with appropriate compatibility to the drug are used. These are mainly polyacrylates, synthetic rubbers, and silicone adhesives.

Electrically conductive adhesives are used in medical applications such as electrocardiogram electrodes and grounding systems for electrosurgery [9, p. 637]. They consist of electrically conductive gels, i.e., moist hydrophilic polymers containing dissolved salt.

Producers and Trade Names: Beiersdorf, Bristol-Myers Squipp, Johnson & Johnson, Lohmann, 3M, Paul Hartmann, SCA Mölnlycke, Smith & Nephew.

1. Origin, Classification, and Industrial Importance of Tars and Pitches

Origin and Classification. *Tars* are liquid or semisolid products obtained by thermal decomposition of natural organic materials. *Pitches* are residues of tar distillation or meltable residues directly obtained by distillation of organic substances. Tars and pitches take their names from the source material. Tars are produced in industrial quantities by low-temperature carbonization, coking, or gasification of fossil raw materials or biomass, e.g., coal, lignite, peat, wood, and oil shale. In addition, tars result as higher boiling liquid pyrolysis products from thermal decomposition of organic secondary raw materials and waste products, e.g., pyrolysis residual oils as byproducts of steam cracking of petroleum fractions to alkenes and from pyrolysis of refuse and plastic waste.

Properties and composition of tars and pitches depend not only on the raw material but also on the temperature conditions during thermal treatment. Thus low-temperature tars are produced during low-temperature carbonization or partial gasification below 700 °C. High-temperature tars are generated by coking between 900 and 1300 °C. The differences in the properties and composition of low- and high-temperature tars are especially marked in case of coal tars. Low-temperature coal tars contain phenols, hydrogenated aromatics, aliphatic hydrocarbons, and alkenes as their main components, together with small amounts of aromatic hydrocarbons. These compounds are generated from two sources: (1) Coal bitumen, the extractable component of coal, which consists of oxygen-, sulfur-, and nitrogen-containing hydrocarbon compounds, and (2) the bitumen which arises additionally from the insoluble components by cracking of aliphatic C – C, C – O, C – N, and C – S bonds, as well as through the removal of side chains (→ Coal Pyrolysis, Chap. 1.). High-temperature coking of coal generates thermally stable aromatics, which are characteristic of high-temperature coal tars. These heat-stable aromatics arise via the following reaction schemes: Paraffins are cracked pyrolytically and dehydrogenated. The resulting alkenes are converted first into hydrogenated aromatics and finally into aromatics. Alkylphenols are dealkylated and reduced to aromatic hydrocarbons.

Lignite tars differ from low-temperature coal tars mainly in an increased content of solid paraffins and a lower amount of cyclic hydrocarbons.

* From Lurgi fixed-bed pressure gasification of coal with oxygen and steam.
** Conradson method.

The main source of paraffins is the extractable montan wax occurring in lignite. The tars are formed by thermal decomposition of initially present and newly formed "bitumen," similar to the case of coal. Tar obtained by high-temperature coking of lignite is similar to low-temperature lignite tar, as lignite bitumen, in contrast to coal bitumen, is already entirely decomposed and volatilized at lower temperatures.

Peat tar properties are determined by the structure of peat, which is a conglomerate of extractable bitumen, humic acid and its salts, and partially decomposed vegetation. In pyrolytic distillation "bitumen" is the source of the bulk of the tar, mainly paraffins. Ketones, methanol, monocarboxylic acids, and phenols arise from the plant components cellulose and lignin (→ Peat, Chap. 3.3.2.).

Wood tars are formed by thermal decomposition of the wood components cellulose, hemicelluloses, and lignin. This gives rise to acetic acid, methanol, ketones and phenols but, in contrast to tars from fossil raw materials, almost no hydrocarbons (→ Charcoal).

History. The discovery of *coal tar* goes back to J. R. Glauber, who in 1658 described the formation of " black oleum" during coal retorting. A patent for the production of pitch and tar by coking of coal with condensation of volatiles was granted in England to J. J. Becher and H. Serle in 1681. In the early 1800s coal tar was initially regarded as an annoying byproduct of town-gas and metallurgical- coke production. In 1822 the first industrial tar distilleries were built in Britain. The light oils obtained were used as solvents, the heavy oils as impregnants for building timber and railway sleepers, and the distillation residue, pitch, for the production of carbon black. In 1845 A. W. Hofmann discovered benzene in the light oil used to produce nitrobenzene as a perfume for soaps, named essence of mirbane. H. Garden (1819) had previously discovered naphthalene and J. B. A. Dumas and M. A. Laurent (1832) anthracene in coal tar. With the discovery of synthetic dyes during the second half of the 1800s, demand for these three aromatic hydrocarbons led to coal tar becoming the main source of raw materials for the flourishing organic chemical industry in central Europe. The first German tar distilleries were built in 1842 in Offenbach by E. Sell, and in 1860 in Erkner near Berlin by J. Rütgers, followed by numerous others.

Lignite tar was obtained by J. G. Krünitz in 1788 as "rock oil" when retorting central German "earth coal." In 1830 Karl Freiherr von Reichenbach isolated the main component, paraffin, by distillation. The lamp oil, obtained as a byproduct, replaced rapeseed oil, which had been used up to then for lighting. After 1858 low-temperature lignite- carbonization plants were constructed in central Germany for the production of tar-based products and town gas. During the 1930s central German lignite tar was mainly processed by hydrogenation to produce motor fuels.

Peat and wood were carbonized in early times. The Egyptians used *wood tar* for embalming corpses. Solid paraffin for candle production and liquid paraffin oil for lamp oil were obtained from *peat tar* or lignite tar during the 1800s.

Industrial Importance. Approximately 15×10^6 t/a of *coal tar* is produced worldwide, mainly in the form of high-temperature tar as a byproduct of metallurgical coke production by horizontal chamber coking (→ Coal Pyrolysis, Chap. 6.2.). Smaller amounts are produced as byproducts of low-temperature carbonization of coal to produce solid smokeless fuel (→ Coal Pyrolysis, Chap. 6.1.) and in pressure gasification of coal by the Lurgi process (→ Coal, Chap. 9.4.). Approximately 100 coal- chemical tar refineries process coal tar to give chemical feedstocks and other aromatic products. Industrial countries with major steel production account for most of the capacity: ca. 50 % in Europe and the CIS, 20 % in North America, and 20 % in South-East Asia, especially China and Japan. In the United Kingdom and India, low-temperature tars are obtained as byproducts of low-temperature carbonization of coal to produce smokeless fuels. Lurgi pressure gasification is a preliminary stage of Fischer – Tropsch synthesis in South Africa.

In contrast to coal tars, *lignite tars* are produced only in a few countries, e.g., as a byproduct of pressure gasification of lignite in the United States (North Dakota), the Czech Republic, Germany (Lausitz), Russia, and China. Lignite is carbonized to produce coke on a minor scale, e.g., in Germany (Rhineland and Lausitz) and India. Normally only the phenolic effluents

are processed, whereas the lignite tars are gasified or burnt within the process. The total amount of lignite tar arising is ca. 10^6 t/a.

Peat tars and *wood tars* arise as byproducts in the production of activated carbon and reductive carbon by carbonization of peat and wood (→ Peat, Chap. 3.3.2., → Peat; → Carbon, Chap. 5.3.). The main producing countries are Russia (peat) and Brazil (wood). The total production of these tars is at most ca. 3×10^6 t/a.

Oil-shale tars are produced by low-temperature carbonization and partial gasification of oil shale, mainly in Estonia (Kiviter process). Approximately 10^6 t/a are produced in this way (→ Oil Shale, Chap. 7.). Other processes involving pyrolysis of oil sand and oil shale are still at the pilot-plant stage.

Pyrolysis residual oils are tarlike byproducts of the steam cracking of naphtha and gas oil to produce alkenes. Approximately 10×10^6 t were produced in 1993. Pyrolysis oils with similar compositions are obtained by thermal decomposition of waste plastics. Industrial large-scale tests are being carried out to develop methods of waste-plastics pyrolysis (→ Plastics, Recycling, Chap. 4.3.).

2. Properties

In general, *tars* are dark or black viscous liquids containing small amounts of emulsified water and dispersed high- carbon solid particles (free carbon, tar sediments) entrained during formation. Organic components may crystallize from high-paraffinic tars at lower temperatures.

Pitches are generally dark or black thermoplastic materials with a broad molecular-mass spectrum. By using selective solvents it is possible to separate pitches into fractions with different properties. At temperatures below the softening range most pitches transform into glass-like solids. At higher temperatures polymerization and polycondensation reactions take place, and pitches change partly from liquid crystal intermediate stages into a nonthermoplastic state and finally into coke [5].

The chemical composition of tars and pitches varies widely and depends essentially on the type of raw materials and the temperature conditions during production. In all cases, multicomponent mixtures are produced that contain aromatic and/or aliphatic hydrocarbons as the main components, together with oxygen-, sulfur-, and nitrogen- containing heterocyclic compounds; phenols; amines; and possibly carboxylic acids, ketones, and aliphatic alcohols as minor constituents. It has been estimated that coal tar can contain more than 10 000 different constituents, most of which have boiling points above 500 °C. Multicomponent eutectics can form, especially in the case of condensed aromatics. The liquid-viscous nature of pitches and many tar oils arises from strong mutual melting-point depression of the individual components [6].

The main properties of different tars are listed in Table 1. Given approximately equal boiling range and pitch content, the density and carbon content indicate the degree of aromatization of tars. Coke-oven coal tars with average densities of ca. 1.2 g/cm^3 and carbon contents >90 % contain the highest fraction of aromatic hydrocarbons, followed by coal low-temperature gasification tars with densities of ca. 1.1 g/cm^3 and carbon contents of ca. 85 %. Smaller amounts of aromatics are found in tars produced by low-temperature carbonization of coal and lignite having densities of ca. 1 g/cm^3 and carbon contents of max. 85 %. Peat and wood tars with carbon contents of only ca. 80 % or even <70 % and varying densities, contain almost no aromatic compounds. Oil-shale tars are hardly or only partially aromatized. However, a high content of aromatic components can be found in pyrolysis residual oils from ethylene/propene plants and from the thermal decomposition of waste plastics if the pyrolysis temperature is at least ca. 700 °C. These pyrolysis residual oils have an aromatic hydrocarbon content of ca. 90 % and higher, similar to coke-oven coal tar, whereas pyrolysis oils contain almost no phenols and only small amounts of heterocyclic compounds due to the raw-material basis. The carbon content falls and the hydrogen content rises with decreasing tar aromatization. A sensitive criterion for the "aromaticity" of tars is the naphthalene content, which is ca. 10 % in coke-oven coal tars and pyrolysis residual oils, ca. 3 % in coal-gasification tars on average, less than 2 % in low-temperature coal-carbonization tars, and max. 1 % for lignite, peat, and wood tars. With increasing geological age of the raw material (i.e., wood $<$ peat $<$ lignite $<$ coal), the content of phenols and solid paraffins decrease, while the

"aromaticity" increases. Thus coke-oven coal tars contain on average ca. 2 % phenols and only traces of solid paraffinic hydrocarbons, whereas low-temperature coal-carbonization tars, lignite tars, and peat tars contain up to ca. 30 % phenols and solid paraffins. High coking values and components that are insoluble in toluene normally indicate a high degree of aromatization.

Table 2. Properties of coke-oven coal tars

Tar properties are investigated with numerous analytical methods. Table 2 contains the analytical values of a typical coke-oven coal tar. Figure 1 shows a gas chromatogram of a coke-oven tar, and Table 3 lists the most important constituents of coke-oven coal tar. Up to now about 600 compounds have been identified in coal tars; together, they account for ca. 55 % of the tar. The remaining, unidentified compounds are mainly pitch components which decompose before they vaporize.

In general, *pitches* are multicomponent mixtures of higher molecular compounds. *Coal-tar pitch* obtained from coke-oven tar is a mixture of condensed aromatic hydrocarbons and heterocyclic compounds. Figure 2 shows a high-pressure liquid chromatogram (HPLC) of coal-tar pitch. HPLC can analyze ca. 70 % of coal-tar pitch [7]. Gel permeation chromatographic investigations indicate in case of higher molecular pitch fractions that they have molecular weights up to approximately 2500 [8]. The highest molecular components, which are partly insoluble, even in pitch, have higher molecular masses. The higher molecular fractions consist of condensed aromatic hydrocarbons and heterocyclics with insignificant fractions containing methyl- or hydroxyl-substituted compounds. The ^{13}C NMR spectrum shows that 97 % of the carbon atoms present are aromatic [9], [10]. Higher molecular pitch fractions contain monomeric aromatics and heterocyclic aromatics, as well as oligomeric systems, in some of which aromatics containing nitrogen and other heteroelements are linked by C – C single bonds or bridges such as CH_2, O, and S [11], [12]. Very large *peri*- condensed systems arise on thermal treatment of normal pitch, whereby the average molecular mass increases and the solubility of the pitch in solvents decreases. Furthermore, anisotropic liquid crystal structures known as "mesophases" are formed [13], [14].

Properties of coke-oven tar "normal" pitch are listed below:

Density at 20 °C	1.27 – 1.28 g/cm^3
Softening point (Krämer-Sarnow)	68 ± 3 °C
Softening point (Mettler)	86 ± 3 °C
Brittle point (Fraass)	30 – 40 °C
Elemental analysis:	
Carbon	92 – 94 %
Hydrogen	4 – 5 %
Nitrogen	1.0 – 1.3 %
Sulfur	0.5 – 0.8 %
Oxygen	1 – 2 %
n-Hexane solubles	40 – 60 %
Toluene insolubles	15 – 25 %
Quinoline insolubles	3 – 7 %
Coking value (ALCAN) (DIN 51 905)	43 – 48 %

3. Processing of Coke-Oven Coal Tar

3.1. Survey

The refining and processing of coke-oven coal tar preferentially isolates aromatic chemicals by a combination of six basic processes (Figure 3):

1) *Distillation* is used for primary separation of crude tar into six fractions: light oil, carbolic oil, naphthalene oil, wash oil, anthracene oil, and pitch. It is also used for further separation of primary and secondary tar fractions.
2) *Crystallization* is used to produce crystalline condensed aromatic hydrocarbons and non-

polar heterocyclics from distillate fractions (e.g., naphthalene, methylnaphthalenes, acenaphthene, dibenzofuran, fluorene, phenanthrene, anthracene, carbazole, fluoranthene, and pyrene). The aromatic oils obtained as filtrates are suitable as components for carbon-black oils, impregnating oils, fuel oils, diesel fuels, fluxing oils, and pitch – oil mixtures such as road tars, refractory pitches, anti-corrosion and protective agents for buildings.

3) *Extraction* with alkalis and acids allows the recovery of phenols and polar nitrogeneous tar bases from light oil, carbolic oil, and filtered naphthalene oil.
4) *Catalytic polymerization* with Friedel–Crafts catalysts yields thermoplastic indene–coumarone resins from light oil fractions from which the phenols and bases have been extracted. The nonpolymerizable component is crude benzole, which together with coke-oven benzol is processed to benzene and benzene homologues; the higher boiling fractions are refined to solvent naphtha and heavy naphtha.
5) *Thermal polymerization* of coal-tar normal pitch yields higher value pitch products such as hard pitch and various special pitches.
6) *Coking* of pitch leads to pitch coke as technically pure carbon which is suitable for further processing into graphite, carbon electrodes, and carburizing agents.

3.2. Primary Distillation

Crude coal tar is generally pretreated prior to primary distillation. The emulsified aqueous solution (up to 5 %) of ammonia, hydrogen sulfide, and ammonium chloride is removed as far as possible. Suspended fine solids (tar sediments) may also be removed.

The simplest procedure for a partial separation of water is to store crude tar at elevated temperatures. Storage for several days at 60 °C decreases the water content by 1 – 2 %. Due to its lower density the water collects at the top of the tank, thus enabling its periodical discharge. To reduce the tar viscosity and increase the settling rate of water, crude tar can be stored in pressure tanks at 100 – 200 °C. This pressure dehydration can decrease the water content to ca. 1 – 1.5 %. The settling rate can be further increased by centrifuging at 6000 – 7000 *g*. Disk centrifuges with discharge nozzles reduce the water content of crude tar down to ca. 0.5 – 1 %.

Figure 2. High-pressure liquid chromatogram of coal-tar pitch [7]

The ammonium chloride contained in tar water dissociates into ammonia and hydrogen chloride above 225 °C, causing corrosion. The ammonium chloride content of crude tar can be greatly reduced by extraction with water prior to mechanical tar – water separation. Another method is to mix in an amount of sodium carbonate or sodium hydroxide solution equivalent to the ammonium chloride content. However, during tar distillation nonvolatile sodium chloride is formed and remains in the pitch, increasing its ash content.

Further impurities of crude tar are dispersed fine solids (tar sediments), which mainly consist of entrained fine coke particles. The partial removal of these sediments takes place together with mechanical water separation by sedimentation during storage. It is also possible to obtain a sediment concentrate from the crude tar by two- or three-phase centrifugal separators either with water as third or as second solid phase. Thus, erosion in pumps, pipes, and valves is avoided and the content of inorganic trace contaminants

Figure 3. Processing of coal tar [1]

in the pitch primary distillation residue is decreased.

Nowadays, partly dehydrated and pretreated crude tar is distilled continuously in pipe stills and rectifying columns. Numerous distillation processes have been developed. They can be divided into flash processes, bottom-circulation processes, and processes in which these two principles are combined.

In *flash distillation* the tar is heated continuously under pressure, usually in a two-stage pipe still. It is then flashed into a system of rectification columns where the oil components are evaporated and fractionated. The first heating step dehydrates and evaporates the light oil, and in the second step the remaining oil components are evaporated, leaving pitch as the residue.

In *bottom-circulation distillation* the rectifying column bottoms are pumped continuously through pipe stills where they are provided with the thermal energy required for distillation.

These two distillation processes differ in the thermal stress on the tar fractions. In the flash process the oil fractions are subject to temperatures well above their boiling range, whereas the distillation residue pitch is not exposed to high temperatures. In the bottom-circulation process, however, the pitch is subject to high temperatures for long periods, but there is only a low thermal stress on the vaporized oil components. As several coal-tar constituents are unstable under distillation conditions, the two distillation processes differ significantly in the yield and quality of certain tar products.

Pipe stills are mostly rectangular or cylindrical, with an inner refractory lining. To maximize the heat utilization of firing gases, pipe stills are divided into radiant and convection zones and are often equipped with air preheaters. The burners of the radiant zone can be operated with gases or liquid fuels of various qualities. The tubes are made of steel; austenitic 18/8/2 chromium nickel molybdenum steels have proved to have especially good corrosion resistance.

As rectifying columns, bubble-cap columns, valve tray columns, sieve-plate columns, packed columns, and combinations thereof are used. Stoneware Raschig rings are used as packing

materials. The lower regions of the dehydration columns and flash columns mostly contain simple cascade trays. In zones with high corrosion risk the columns consist of high-grade stainless steel or cast iron, otherwise of mild steel.

To separate high-boiling tar fractions the columns normally operate under vacuum. In some processes steam is injected to lower the evaporation temperature. Heat of condensation and the thermal energy contained in the flowing bottom products are transferred via heat exchangers to the crude tar and its intermediate products to lower the total energy demand.

The *GfT/Koppers* continuous tar distillation process is shown in Figure 4 as an example of flash distillation. In the first step the crude tar is heated to ca. 160 °C in the pipe still and then flashed through an expansion valve into the middle of the atmospheric dehydration column. The pressure before the expansion valve is up to 10 bar. Light oil and water evaporate in the dehydration column, which is equipped with bubble and overflow trays, and are separated into two phases after condensation. Part of the light oil is refluxed to the top of the dehydration column. The dehydrated (topped) tar as column bottom is preheated in a heat exchanger by the hot pitch stream, then it is heated under pressure to 360 °C in the second stage of the pipe still. At this temperature it is flashed in the pitch column at a pressure of 100 – 130 mbar. The pressure before the expansion nozzle is up to 5 bar. To take off the high-boiling anthracene oil II above the flash chamber, there is a column, filled with Raschig rings, which is dephlegmated at the top with the lower boiling anthracene oil I. The column tops of the vacuum system are refluxed with a split stream of the oil fraction taken from the bottom of the next column. The bottom product of the wash oil column is directed via a side column to evaporate the remaining naphthalene. This side column is additionally heated by bottom circulation, yielding an improved rectification efficiency. Concentrated ammonium chloride is extracted with water from the bottom product of the wash oil main column before the oil is refluxed to the top of the anthracene oil column. This continuous removal of ammonium chloride prevents clogging and corrosion of the column by the salt, which condenses to form a solid in the temperature range 180 – 200 °C. The tar oil fractions anthracene oil I, wash oil, and naphthalene oil are separated as column bottoms. Carbolic oil is condensed in the final condenser as the top product of the naphthalene column. The uncondensed gases and vapors are extracted with oil and water before entering the vacuum equipment. Light oil and naphthalene vapors are extracted in the oil scrubber with cooled wash oil. Hydrogen sulfide is removed with water in the water scrubber. The heat consumption of the total plant is ca. 900 MJ/t of wet crude tar.

Figure 5 shows a diagram of the *Rütgers process* for continuous tar distillation using the bottom- circulation principle. Each of the main rectifying columns has its own pipe still for bottom circulation to achieve independent control of the column reflux. Condensing water, light oil vapors of the dehydration column, and waste heat vapor preheat the crude tar to 105 °C. Afterwards the crude tar is pumped into a dehydration column which contains cascade trays. The bottoms of the dehydration column are circulated through a pipe still and kept at 150 °C. After intermediate storage the dehydrated topped tar is passed through to heat exchangers where the heat of condensation of carbolic oil and the heat of pitch is used. The topped tar, at ca. 250 °C, enters the middle section of the carbolic oil column, which is operated at atmospheric pressure and is equipped with valve or Perform trays in the lower part and, bubble trays for example, in the upper part. The pipe still, with a discharge temperature of 380 °C, allows adjustment of the reflux ratio up to 16 : 1. A distillate fraction in the carbolic oil column is cycled to the top of a side-stream column where the naphthalene oil fraction is taken as a vapor from its base. The main-stream bottom product is led via heat exchangers to the methylnaphthalene column, which is run with a top pressure of 250 mbar and which also contains a packing or Perform trays as well as bubble trays. The reflux ratio of this column is up to 17 : 1. A methylnaphthalene fraction is obtained as top product. The top vapors are condensed in a low-pressure steam generator. A wash oil fraction is taken from a side column and a fluorene fraction is taken as a further side stream of the main column. The bottom product of the methylnaphthalene column is led to the anthracene-oil packed column with a top pressure of 90 mbar. Its top product is anthracene oil, and the bottom product is normal pitch. This column only requires a reflux ratio of 1.5 : 1. The

condensation heat of the anthracene oil is used for steam generation.

Besides the product flows described, other column interconnections are possible. Due to the high reflux ratios in efficient rectifying columns the tar oils are separated into many single fractions. Thus a high-yield extraction of technically pure components can be achieved. For example, the naphthalene oil fraction contains up to 90 % or more of the naphthalene occurring in crude tar at a concentration up to 90 % (crystallizing point up to 75 °C). Despite the increased energy needed for high reflux ratios, the heat requirement of the plant is only ca. 880 MJ/t crude tar due to the heat recovery system.

If the production of coal-tar pitch rather than tar aromatics and oils is the main aim then the primary distillation of crude tar should be combined with a thermal treatment at increased temperature and longer time under pressure. This is the case, for example, in the production of binders or coke for carbon and graphite electrodes.

The *Cherry-T process* of Osaka Gas [15] serves as an example of such a procedure. In this process water and light oil are separated from the crude tar as a first step, usually in a dehydration column. The dehydrated tar is heated in a pipe still to almost 400 °C and afterwards thermally polycondensed in a pressure reactor. After this reactor, a flash column is used for oil/pitch separation. If necessary, the oil can also be treated thermally in a second pressure reactor. Then, after additional flashing, a secondary oil pitch and nonpolymerized oils are obtained. The total yield of primary and secondary pitch is ca. 75 %, compared with 50 – 55 % for tar distillation without intensified thermal treatment.

Whereas in the Cherry-T process, electrode pitches are the main products of primary processing, pitch coke is the main product when tar distillation is coupled with a *delayed coker* (→ Oil Refining, Chap. 3.6.4.1.). Some Japanese plants use such a combination (see Section 3.3). Here only light, carbolic, naphthalene, and wash oils are separated by primary distillation. Soft pitch obtained as residue is pumped into the bottom of a combination tower where it is distilled together with coker oil. The bottom product of the combination tower is transferred to the pipe still of the delayed- coking plant where it is heated to almost 500 °C and pumped into the delayed- coking drum (see Section 3.3).

Nondistillation processes for the primary processing of coke-oven coal tar, such as liquid or supercritical extraction and hydrocracking, are presently not used in large-scale production.

3.3. Processing of Coal-Tar Pitch

3.3.1. Cooling

Approximately 50 – 55 % of the products of a coal tar primary distillation is a coal-tar normal pitch with a softening point of 68 °C (Krämer – Sarnow). This is either processed directly in the liquid state or solidified by cooling, which converts the thermoplastic pitch into its glassy state.

Modern pitch- cooling processes operate continuously and use water as cooling medium. The pitch is obtained in granulated form.

The problem of continuous pitch cooling is to obtain a rapid heat transfer despite the relatively low thermal conductivity of pitch. If the granules do not cool completely, undesired agglomeration during storage and transport can occur. For various applications the pitch granulate must be moisture-free; therefore, cooling is followed by drying. Several continuous processes for direct cooling of molten coal-tar pitch with water have been developed.

Figure 6 shows the diagram of the Rütgers pencil-pitch process [16]. Relatively thick strings are formed by pumping pitch through

heated nozzles directly into water flowing cocurrently. The water acts as cooling and transport medium. Before the liquid pitch is formed by the nozzles, it is cooled in a heat exchanger that produces low-pressure steam. The nozzles are shaped such that by adjusting the temperature and water/pitch ratio, a pitch string without internal water inclusion is obtained. The cooling water and the solidified pitch string run together through a cooling tube 20 – 25 m long. This tube may be bent to shorten the equipment. Each nozzle has its own cooling tube to prevent the warm, thermoplastic pitch strings merging. At the end of the cooling tube the outer skin of the pitch strings at least has cooled and solidified. The strings can be deposited together on a slowly moving conveyor belt running submerged in a long cooling-water basin. The cooling water is cooled and recycled. At the end of the cooling section the conveyor belt removes the cold, solidified pitch strings from the water. They pass a dryer whose airstream is heated by the low-pressure steam produced in the heat exchanger. The dried pitch strings are air-cooled and then loaded into transport and storage containers. During loading the pitch strings break into short, air- conveyable pieces. This process is also applicable to other pitches with different softening points. The throughput capacity is 1 – 2 t per nozzle per hour.

3.3.2. Production of Electrode Pitch

Electrode pitches are the most important products derived from coal-tar pitch. They are used as reactive binders, especially for the production of carbon anodes for aluminum production by electrolysis (→ Aluminum, Chap. 4.2., → Aluminum, Chap. 4.3.) and furthermore as binder and impregnating pitches for the production of graphite electrodes for electric steelmaking (→ Carbon, Chap. 4.1.; → Steel, Chap. 3.3.2.).

Electrode pitches should have good caking and binding properties towards electrode cokes (petroleum cokes, pitch cokes), the solid components of the electrode paste. On heating, electrode pitches should give a high yield of a high-strength coke. Medium and higher molecular pitch fractions are mainly responsible for the caking and binding properties. They are analyzed by solvent fractionation (e.g., quinoline insolubles, QI; toluene insolubles, TI; β-resins = TI − QI). The volatile matter of the electrode pitch should degas smoothly to prevent cracking during carbonization of the electrode paste. Moreover, electrode pitches should wet electrode coke particles well and should have a desirable viscosity – temperature behavior and their properties should not change significantly on hot storage at temperatures of, e.g., 200 – 250 °C. The content of ash-forming constituents should be low. Table 4 lists typical characteristics of various electrode pitches. Bench-scale processes have been developed that allow the quality properties of electrode pitches to be determined more precisely. It is now possible to produce test electrodes with electrode coke on a laboratory scale. These electrodes are tested according to various methods [17], [18]. Quality aspects of the test electrodes include high mechanical strength, high electrical conductivity, and low air permeability, as well as low air reactivity at, e.g., 525 °C and reactivity to CO_2 at, e.g., 1000 °C [19], [20].

The properties required for electrode pitch are generally not fulfilled by normal pitch from conventional coal-tar primary distillation. The aim of production processes for electrode pitch is to increase the pitch coking value. This is achieved either by thermal condensation and polymerization of pitch components in secondary processes or by gentle distillation of vaporizable pitch components integrated with the tar distillation. In both processes the softening point and the content of medium-molecular β-resins are increased, and in the thermal condensation and polymerization process, the amount of quinoline insolubles rises. These "secondary" quinoline insolubles, generated during thermal retreatment, mainly consist of liquid crystalline carbonaceous mesophases. These mesophases advantageously increase the coking value of total pitch, but at the same time generally decrease its wetting ability. Therefore, in many cases electrode pitches produced without mesophase formation are preferred for electrode production [21].

Figure 7 shows the flowsheet of a thermally gentle electrode-pitch production. The process is part of the coal-tar primary distillation. In this case the coal-tar primary distillation (see Fig. 5) is extended by a flash column. By regulation of

temperature and vacuum it is possible to directly control the desired increased softening points and the coking values related therewith.

The Cherry-T process of Osaka Gas (see Chap. 3.2) is a continuous thermal pitch-condensation process forming part of the coal-tar primary distillation. This process gives a high yield of electrode pitch from coal tar in two different qualities. In the first step a primary pitch yield of 55 – 60 % from coal tar is achieved. The pitch has a softening point of 80 – 100 °C, 31 – 38 % toluene insolubles, and 8 – 14 % quinoline insolubles, thus having a β-resins content of ca. 22 %. In the second step, further thermal treatment of the flash oil from the first reactor gives 40 – 50 % of a secondary pitch with a softening point of 70 – 90 °C, 23 – 31 % toluene insolubles, and a very low amount of quinoline insolubles (max. 2 %) [22].

Not only the production conditions for electrode pitches but also the choice of parent coal tars is important. The desired pitch components may already have been formed to a large extent in the coal tar. Moreover, the tars have to meet the requirements concerning the content of inorganic contamination, which very often require a separation of these microparticles by centrifugation or extraction. For use as binder pitches for carbon anodes in aluminum production, for example, a low content of zinc and iron compounds is important. Under the conditions of aluminum oxide electrolysis in the melt, elemental metals are formed together with aluminum at the cathode, thus reducing the purity of the aluminum product. Furthermore, the content of alkaline earth and alkali metal compounds should be as low as possible because they catalyze the reaction of CO_2 with the carbon anode. In the case of impregnating pitches it may also be necessary to partly remove the highest molecular mass quinoline insoluble α-resins from coal tar, as the impregnating behavior depends upon the content of α-resins and upon their particle size distribution. On the other hand, α- and β-resins considerably contribute to the stability of the pitch coke skeleton formed from electrode pitch, thus giving the mechanical and thermal stability of carbon and graphite electrodes.

For large-scale production of electrodes, bituminous binding agents other than coal-tar pitch have not gained acceptance. The reason is the good coking behavior of coal-tar electrode pitches due to the high content of condensed aromatics and fixed carbon. Coal-tar pitch has the highest carbon content of comparable bituminous binding agents. In contrast to petroleum asphalt and coal extracts, the carbon content of coal-tar pitch is considerably above 90 %, on average ca. 93 %. The atomic C/H ratio is 1.7 – 1.8 compared with, for example, 1.3 for coal extract from the solvent refined coal (SRC) process and 0.8 for high-vacuum bitumen with a comparable softening point [23]. It is only possible to produce aromatized petroleum pitches from

Figure 7. Flowsheet of a coal-tar primary distillation with integrated electrode-pitch fabrication (Rütgers process)
a) Pitch/anthracene oil column; b) Reboiler; c) Flash column

strongly aromatized residues of catalytic petroleum cracking by thermal treatment. These may serve as substitutes for coal-tar electrode pitches in some situations [24], [25].

Despite the advantages of coal-tar pitch as electrode binder, it does have environmental and toxicological drawbacks. Coal-tar pitch has a high content of cancerogenic polycyclic aromatics, especially benzo[*a*]pyrene. However, the uptake of harmful polycyclic aromatic hydrocarbons can be avoided if pitch fumes and dusts are not handled or inhaled. Nevertheless, attempts have been made to reduce the benzo[*a*]pyrene content of electrode pitches. The physical removal of the cancerogenic polycyclic aromatic hydrocarbons by extraction or distillation is technically possible. The softening point of the pitch increases on removal of these low-molecular compounds. Bench-scale experiments showed that it is possible to obtain carbon electrodes with improved technical properties when using such high-melting electrode pitches [26]. In an electrode pitch with an increased melting point of 170 °C, for example, the benzo[*a*]pyrene content is decreased by $> 60\,\%$, down to $0.3 - 0.4\,\%$. A further increase of the melting point up to, for instance, 260 °C by a $> 99\,\%$ reduction of the benzo[*a*]pyrene content to less than 100 or 50 ppm is possible in principle. For practical applications, however, modification of the electrode production process by using a different mixing technology for the electrode masses, or adjustment of the softening point is necessary [27].

3.3.3. Production of Pitch Coke

Like calcined petroleum coke, pitch coke is used as electrode coke, the solid component for the production of carbon and graphite electrodes. In addition, technically pure carbon pitch coke is used to produce other carbon and graphite materials, especially for high-temperature and chemically resistant equipment. It is also used as conductive filler in carbon brushes, batteries, plastics, and brake linings; as a carburizing agent in steel and cast-iron production; as adsorption coke for water purification; as an almost ash-free solid reducing agent in metallurgy and chemistry; and for the production of highly isotropic graphite for nuclear reactors. Specifications of different pitch cokes are listed in Table 5.

Table 5. Properties of pitch cokes

* Measured on graphite rods, 20 – 200 °C.

The most important processes for producing pitch coke are:

1) Discontinuous high-temperature coking of hard pitch in normal coke ovens with gas heating and liquid feeding, used especially in the CIS.
2) Discontinuous coking of soft pitch by the delayed- coking process in Japan and China.
3) Continuous hard-pitch coking in an indirectly heated rotary-drum reactor (still in development).

Hard pitch with a softening point > 150 °C (Krämer – Sarnow) can be obtained either from the normal pitch produced by continuous tar distillation by dehydrogenative condensation with atmospheric oxygen (air blowing) or solely by thermal treatment, similar to electrode-pitch production processes.

In the air-blowing process, air is blown through liquid normal pitch at 300 °C in a retort directly after coal-tar primary distillation [28]. There is an air distributor at the bottom of the retort, and the air is either sucked or blown through the pitch. The reaction is exothermic above 300 °C and takes place without additional heating. The temperature of the retort contents rises to ca. 400 °C. The main product is a hard pitch which can be processed to coke with a yield of up to 83 %. The byproduct pitch distillate can be converted into a secondary hard pitch by distillative thermal treatment and air blowing. By using a mixture of primary and secondary hard pitch, different pitch- coke qualities can be obtained in the subsequent coking process.

The thermal condensation of normal pitch to hard pitch is usually carried out by continuous treatment of normal pitch in pipe stills under pressure followed by flash distillation to remove vaporizable components. Compared to the air-blowing process, the yield of hard pitch is lower, but the yield of high-boiling aromatic oils is higher.

In discontinuous *pitch coking in horizontal coke ovens* hard pitch is pumped at a temperature of above 300 °C into heated pitch tanks. In the Koppers process [29] several oven blocks, each with, e.g., five pitch- coke ovens, can be fed by these tanks. The hard pitch is pumped continuously via a ring main from the pitch tanks to the oven blocks. The liquid hard pitch is pumped in portions over a period of several hours into the coke ovens from this ring main. The final coking temperature can be up to 1200 °C, and the coking time 14 – 24 h. The pitch- coke yield is ca. 70 %. The pitch- coke oil byproduct can be used for secondary-pitch production. By mixing this pitch with the primary pitch, the quality of pitch coke can be varied and the pitch- coke yield increased to 80 – 85 %. Under these conditions ca. 250 m^3/t process gas, containing ca. 80 vol % hydrogen and ca. 12 vol % methane, are generated as a byproduct. This gas can be used for the production of hydrogen, or as low- calorific gas for heating the coke ovens and pitch tanks. With heat requirements of ca. 18 MJ per tonne of hard pitch, about 80 % of the process gas is required. Analogous to metallurgical coke production, after carbonization the pitch coke is pushed mechanically out of the horizontal chamber of the coke oven and cooled in aquenching car by spraying with a calculated amount of water. It is possible to achieve a water content of 1 – 2 % in spite of the high porosity of pitch coke. Due to the high carbonizing temperature, the pitch coke produced does not require secondary calcination.

The second process for production of technical pitch- coke from coal tar is *delayed coking*, well known from petroleum refining (→ Petroleum, Coke). To produce a pitch coke with a low volatiles content a second calcination step is required. Soft pitch containing high-boiling aromatic oils, obtained by primary distillation of coal tar, is used as feed. The soft pitch is

pumped into a combination column, the bottoms of which are fed to the pipe still of the delayed coking plant.

Figure 8 shows the process flow sheet for production of pitch coke from coal-tar soft pitch by delayed coking using the Lummus process as applied in Japan and China [30]. The soft pitch coming from the coal-tar primary distillation at 150 °C is heated in a heat exchanger by the heavy oil of the combination column and then pumped into the bottom of this column. The coker oil of the delayed- coking plant is also added to the column. Light oil, middle (naphthalene) oil, and heavy (anthracene) oil fractions are taken from the combination column. The bottoms of the column are heated in a pipe still to 485 – 510 °C by gas or fuel oil. Then they are fed from below into one of two coker drums via a switching valve. In these drums the delayed coking of pitch takes place during a 24 h cycle with a residence time of 12 h at a pressure of, for example, 5 bar. When the first coker drum is full, the feed is switched to the preheated empty coker drum. After switching, the full drum is steamed for 2 h to remove residual coker oil, which is mainly present in the upper part of the coker drum. The oil obtained is recycled to the combination column. After steaming, the coke charge is cooled directly with water. Then the coke is cut out by a high-pressure water jet, which takes 5 – 7 h. The green coke obtained is dried, broken, and calcined in a hearth furnace or a rotary drum. The pipe still and the calciner can be heated with coker gas arising as the noncondensable top product of the combination column.

Normally the green- coke yield is at least 60 % of the soft pitch fed, with approximately 3 % process gas and 35 % coker oil as byproducts. The combination column yields ca. 10 % light and middle (naphthalene) oil, as well as ca. 25 % heavy (anthracene) oil. The coker gas contains ca. 50 % hydrogen and 50 % methane. The middle oil has a boiling range of 180 – 310 °C and contains ca. 30 % naphthalene. The heavy oil has a boiling range of 265 – 400 °C and a composition that differs from that of an anthracene oil from normal continuous tar distillation. Under the conditions of pressure carbonization in the delayed coker, some distillable tar aromatics are preferentially converted to coke. The green coke still has 7.5 – 9.5 % volatiles, which are removed to a residual content of < 0.5 % by calcination at up to 1300 °C.

Highly anisotropic cokes, known as *needle cokes*, are obtained via intermediate liquid-crystalline mesophases by delayed coking of pitches from which the α-resins (quinoline insolubles) have been largely removed by filtration [31] or extraction [32]. These needle cokes are used for the production of ultra-high power (UHP) graphite electrodes with high electrical conductivity and low thermal expansion coefficient.

The carbonization of hard pitch in an indirectly heated *rotary drum reactor* [33], [34] is a continuous pitch- coke production process. Hard pitch is pumped into an indirectly fired rotary drum reactor where it is carbonized with a residence time of 0.5 – 1.5 h at an inner-wall temperature of 500 – 800 °C. The gases and vapors arising are pumped in countercurrent to the carbonizing pitch, if necessary together with an inert gas. The green- coke yield is 70 – 75 % of the hard pitch feed. The grained coke has volatile matter content of ca. 3.5 wt % and relatively high strength and density. It is calcined without precooling in a second directly heated rotary drum reactor at up to 1300 °C. The yield of calcined coke is ca. 90 % of the green-coke feed, and 65 – 70 % of the hard pitch input. The advantages of this continuous process compared with the discontinuous processes of horizontal chamber coking and delayed coking are the possibility to adjust the residence times and heating periods, thus yielding a more homogeneous pitch coke.

3.3.4. Production of Special Pitches

Hard pitches, soft pitches, and extractive pitches produced by solvent extraction with considerably decreased content of α-resins (primary quinoline insolubles) are special pitches that are intermediate products of pitch carbonization. Other special pitches include plasticized pitches for protective coatings, pitches used for pitch – polymer combinations, and road-binding agents which are compatible with polymers and bitumen, as well as the newly developed and produced mesophase pitches and high-melting isotropic pitches for further processing to carbon materials.

Figure 8. Production of pitch coke by delayed coking
a) Combination column; b) Pipe still; c) Coker drums; d) Rotary kiln; e) Rotary cooler; f) Decanter; g) Condenser

Soft pitches with increased coking values are used as *refractory binders*. They are reactive binding agents for the production of dolomite and magnesite bricks used especially for the lining of steel converters. During brick calcination a binding coke skeleton is formed by carbonization of the soft pitch, which considerably increases the compressive strength of the preform and counteracts corrosive attack by slags. Refractory binder pitches with increased coking values are obtained by adjusting hard pitches with high-boiling aromatic oils to give the desired softening point. Also soft-pitch mixtures with phenolic resins or their precursors are used. Special formulations contain less than 50 ppm benzo[*a*]pyrene.

For the production of *anticorrosion protective coatings* (→ Paints and Coatings, Chap. 2.14.4.) the plasticity range (difference between softening and brittle point) of 30 K of coal-tar normal pitch is too low. To increase this plasticity range to 100 K or more, hard pitches with a high content of toluene insolubles are adjusted to the desired softening point with high-boiling tar oils, preferably by adding crystalline tar aromatics. A further increase in the plasticity range is obtained by hot-mixing these pitches with extenders such as finely ground coal, minerals, diatomaceous earth, or fly ash. Such plasticized pitches are used for long-term anticorrosion pipe coatings and as sealing compounds. The advantages compared with the bitumen coatings are the excellent resistance of coal-tar pitch to moisture, bacteria, fungi, mineral oils, and gasoline. When pitch coatings are used together with cathodic pipe protection the low water absorption of coal-tar pitch is important. The water content of a 2.5 mm tar-pitch coating is only 0.3 – 0.6 % after prolonged storage in water. Plasticized pitches without extenders are used as dip- coating agents for protecting cast-iron pipes.

To meet especially high anticorrosion requirements, coal-tar pitches are combined with polymers [35]. Especially suitable for such *pitch – polymer- combinations* are epoxy resins, polyurethanes, and some elastomers (→ Paints and Coatings, Chap. 2.14.5.). Normally two-pack systems are produced for epoxy resin combinations. One component contains the nonhardened epoxy compound dissolved in a compatible special coal-tar pitch, and the other contains the hardener for the epoxide compound. After combination of the components the epoxy resin polymerizes and incorporates the pitch components. Usually low molecular-mass liquid epoxy resins are combined with soft coal-tar pitches. After chemical hardening, coatings with high-temperature stability and resistance to chemicals are obtained. Pitch – polyurethane two-pack systems are produced and processed similarly. One component contains the special soft coal-tar pitch and the polyol, and the other the polyisocyanate. In combination with polyurethanes, one-

pack systems that cure by reaction with atmospheric moisture are also feasible. Other polymers and elastomers are mixed directly with the hot liquid pitch, whereby miscibility gaps and the decomposition temperatures of the polymers must be taken into account. It is also possible to add high-boiling or unvaporizable, preferably aromatic homogenizing agents.

By using high-boiling tar aromatics as homogenizing agents, soft coal-tar pitches with a low content of α-resins can be combined in any ratio with appropriate, preferably naphthene-based bitumens. Carbobitumen, a highly deformation resistant *road binding agent*, is a blend of soft pitch and hard bitumen, containing 20 – 30 % of a special pitch. The pitch is enriched with high-boiling crystalline aromatics [36], [37]. These crystalline aromatics cause a separation of microcrystals in the pitch – bitumen matrix when cooled to ca. 100 °C. These microcrystals cross-link the thermoplastic system and harden the binding agent at lower temperatures. Thus carbobitumen is harder at temperatures below 70 – 80 °C and, therefore, more deformation resistant than the road bitumen usually used. At higher temperatures, however, it is less viscous and, therefore, can be applied at lower temperatures than road bitumen.

Normal pitches, hard pitches, and special pitches with carbon fillers and polymers are suitable as reactive additives for *cocarbonization of weak- coking coal blends* in amounts of 2 – 10 %. The mechanical strength of the metallurgical coke produced in horizontal chamber-coke ovens increases on addition of an amount of pitch ascertained by laboratory tests [38], [39]. With increasing temperature the pitch wets the coal grains in the coke-oven chamber. It partially dissolves the coal macerals in the softening range of the coal. During carbonization above 450 °C inert macerals and solid leaning agents such as coke dust or petroleum coke are also brought into the generated coke skeleton. Used plastics, for example, can be utilized as additives. These polymers should first be subjected to cothermolysis with pitch, to obtain a resistant reactive additive as liquid phase in the coal-softening range [40].

Further special pitches are fine-grained *foundry pitches* produced by spraying. They have a high softening point and high coking value. They serve as binding agents for the production of foundry molds. Another special pitch is *fiber-pipe pitch* which has a low content of α-resins. This is used as impregnating material for cellulose fibers in the production of pitch fiber pipes. *Clay pigeon pitch* is used as a brittle binding agent with increased softening point for clay pigeons used in sport shooting.

Mesophase pitches are pitches with a high content of carbonaceous mesophases (see Chap. 2). They are produced by heat treatment of pitches that have been filtered or extracted to remove primary α-resins [31]. By heat treatment, mesophase spherules are formed, which can be separated from the isotropic pitch matrix by settling and/or by solvent fractionation. Pitch pre-fractionation with solvents or supercritical extraction is often carried out before thermal mesophase formation. Two-step thermal pitch treatment is also utilized. In the first step the especially reactive pitch aromatics are separated by condensation to give secondary quinoline insolubles. The second thermal treatment step leads to mesophases with low to medium molecular mass and correspondingly low viscosity, which can be advantageous. Mesophase pitches can also be produced from special petroleum pitches, hydrogenated coal-tar pitches, and pyrolysis residual pitches. By using different processes special properties can be achieved [41]. Mesophase pitches also can be produced by catalytic polycondensation of naphthalene and its homologues and higher condensed polycyclic aromatic hydrocarbons in the presence of homogeneous Friedel – Crafts catalysts. Thus, after 2 – 17 h at 140 – 180 °C 80 – 100 % mesophase pitches with a yield of 50 – 80 % are formed from naphthalene, 1,1-binaphthylanthracene, and 1,2-benzanthracene and from a 1: 1 mixture of naphthalene and phenanthrene by reaction with aluminum chloride/copper(II)chloride [42]. From naphthalene it is possible to produce mesophase pitches by using HF/BF_3 catalysts, either by one step at 260 – 300 °C, or by two steps, the first at 80 °C and the second at 400 – 480 °C under vacuum or pressure [43]. Instead of naphthalene, 1-methylnaphthalene, 2-methylnaphthalene, or mixtures thereof can also be used. Here mesophase pitches are formed by using HF/BF_3 at 260 °C under a pressure of ca. 30 bar in 4 – 5 h with a yield of 80 – 90 % [44].

Mesophase pitches and high-melting isotropic pitches are intermediates in the production of new forms of technical carbon such as anisotropic and isotropic carbon fibers, mesocarbon microbeads, and sinterable carbon powders [41]. In their production the special pitches are normally first stabilized by oxidation after preforming by melt spinning or fine grinding and are then partly or entirely carbonized. For the production of high-modulus carbon fibers from mesophase pitches various processes have been developed (→ Fibers, 5. Synthetic Inorganic, Chap. 5.4.). Some of these processes have been used commercially. Mesophase microbeads and sinterable carbon powders can be pressed isostatically without additional binding agents and converted by thermal treatment into highly dense isotropic carbon materials [41]. In the last few years isotropic fine-grained carbon materials have found a wide range of applications, as have carbon fiber reinforced carbon materials (CFC) [45]. Widespread areas of application for these carbon materials can be predicted for the future, especially in energy and transport technology. This is due to their low density compared to metals such as steel and aluminum, their mechanical strength over a wide temperature range, and their excellent properties at temperatures up to 4000 °C if protected against oxidation.

3.3.5. Pitch – Oil Blends

Coal-tar pitches are highly soluble in various tar oils. For manufacturing of pitch – oil blends (refined tars) the liquid pitch is mixed with tar oils.

Road tars based on pure coal tars are blends of normal pitch with middle oils (boiling range 170 – 270 °C), heavy oils (boiling range 270 – 300 °C), and anthracene oils (boiling range above 300 °C). The content of normal pitch is between 60 and 80 %. These road tars are suitable for surfacing low-traffic roads. The advantages of road tars for this purpose are good adhesive strength, quick rock wetting due to their content of polar compounds, and their property of gradual surface resinification. The middle and heavy oil components evaporate during setting, leaving as the actual binder a soft pitch consisting of anthracene oil and normal pitch. The setting speed depends on the initial viscosity and the pitch/anthracene oil ratio. Normal setting road tars have a pitch/anthracene oil ratio of ca. 3.5: 1. By increasing the ratio of anthracene oil II (boiling range above 350 °C) and anthracene oil I (boiling range up to 350 °C), aging-resistant road tars can be produced. Bitumen- containing road tars include, for example, 15 % asphalt basic distillate bitumen with low oil content; bitumen-rich road tars contain 35 – 40 % bitumen, and *pitch bitumen* contains 70 – 85 % bitumen. These tar – bitumen blends with increased or predominant bitumen components combine the advantages of tar (good setting properties, resistance to mineral oil and fuel, easy processability, and good road grip) with those of bitumen (low temperature dependence of viscosity and wide plasticity range). Carbobitumen is a specially deformation resistant pitch – bitumen blend (see Section 3.3.4).

Besides bitumen, plastics such as poly(vinyl chloride), polystyrene and epoxy resins are used for the modification of road tars. Thermosetting tar – epoxy resin combinations (see Section 3.3.4) are particularly suitable for highly exposed road surfaces and airport runways due to their good wear properties and their resistance to liquid fuels.

Roofing tars used as impregnating, coating, and adhesive material for tarred felts and tarred sealing webs are usually blends of pitch and filtered anthracene oil. By using plasticized pitches or by adding extenders the plasticity and temperature stability of roofing tars is improved considerably. Tarred felts produced in this manner have the same temperature stability as bitumen felts. Moreover, they have a high resistance to water, microorganisms, and plant roots.

Pitch paints are solutions of coal-tar pitch in highly volatile aromatic solvents such as light and heavy tar-oil naphtha. Normally plasticized pitches are used or extenders are added. Like the plasticized pitches themselves, which are processed while hot, pitch paints have excellent resistance to water, bacteria, and chemicals. Anticorrosion and building-protective coatings are applied, for example, as underwater protection and as protective paints for steel, concrete, and underground brickwork [35].

Effective anticorrosion protective coatings are obtained by combining pitch with polymers. The best-known *pitch combination coatings* are two-pack systems based on soft pitches and epoxy resins (see Section 3.3.4). The coatings

are resistant both to low temperatures and high temperatures up to 100 °C. They are resistant to fresh and salt water, moderately strong mineral acids and alkalis (except ammonia), salt solutions, lubricating oils, and nonaromatic motor fuels. Two- and one-pack pitch – polyurethane coatings have a similar range of applications.

3.4. Processing of Tar Distillates

This chapter deals with the further processing of primary tar distillates to fractions and the various aromatic oils. The processing to technically pure aromatic compounds is dealt under separate keywords. Only the processing to technically pure phenols and pyridine bases is described in more detail here.

3.4.1. Processing of Anthracene Oil

In the primary distillation of coal tar, ca. 20 – 30 % of the crude tar distills as anthracene oil, which at room temperature is a semisolid, green-brown, crystalline material with a boiling range of ca. 300 – 450 °C. In most primary distillation plants two fractions are produced: the larger fraction being low-boiling anthracene oil I, and as the smaller, high-boiling anthracene oil II. Anthracene oil I contains phenanthrene, anthracene, and carbazole, whereas fluoranthene and pyrene are concentrated in anthracene oil II.

The crude anthracene oil or anthracene oil I is cooled in water- cooled discontinuous or continuous crystallizers and partially crystallized to give a filtered anthracene oil and anthracene residues. Filtered anthracene oil does not crystallize at normal temperature. The discontinuous cooling process is usually used. Anthracene oil at 80 – 100 °C is pumped from primary distillation into cylindrical vertical stirred coolers. It is cooled over 24 – 36 h to 20 – 30 °C by indirect water cooling. Early sedimentation of crystals is prevented by a slowly rotating stirrer (ca. 15 rpm). After cooling the crystal slurry is discharged via a gate through the conical lower part of the cooler and centrifuged with a peeler centrifuge. The crude anthracene oil yields 10 – 15 % anthracene residues and 85 – 90 % filtered anthracene oil. The residues are further processed to anthracene, phenanthrene, and carbazole.

Filtered anthracene oil I and high-boiling anthracene oil II are important blending components for technical *aromatic oils* and pitch – oil mixtures. Aromatic oils with anthracene oil as main component include carbon-black oils, impregnating oils (creosote), medium fuel oils, special diesel fuels, gasometer oils, fluxing oils, naphthalene wash oil and numerous others. Table 6 lists specifications for some of these aromatic tar oils.

Carbon-black oils. Due to their low sulfur content and high aromaticity, coal-tar oils are high-value raw materials for carbon black. Carbon-black oils obtained from coal tar have, due to their high content of condensed aromatics, the highest Correlation Index (Bureau of Mines). They are pyrolyzed at ca. 1500 °C by the furnace-black process to yield filler blacks, mostly for rubber, and pigment blacks, mainly for printing inks. Depending on the required quality of the carbon black the yield is 40 – 70 % (→ Carbon, Chap. 6.).

Impregnating oils (creosote) obtained from coal tar are important for long-term wood preservation (→ Wood, Preservation, → Wood, Surface Treatment). The aromatic components of anthracene oil and other tar-oil components have, when mixed, strong antifungal properties and significant pesticidal properties for wood pests such as the house long horn beetle (*Hylotrupes bajulus*), the ship worm (*Toredo navalis*), anobium beetles (*Anobium punctatum*) and termites, and furthermore inhibit dry-rot fungi. Railway sleepers, telegraph poles, pit props, timbers for use in water and other building timbers are protected against decay and insect damage over a long term by vacuum – pressure impregnation with tar oils. Coal-tar impregnating oils are not washed out by water, are noncorrosive, and have high electrical resistance. The service life of such impregnated woods is prolonged from 5 – 15 years to 30 – 50 years. The various types of impregnating oils are blends of filtered anthracene oil, wash oil, and filtered naphthalene oil.

Fuel oils based on coal tar have a short, hot flame with high radiation intensity due to their high carbon content. Because of these properties they are used in various metallurgical plants. Coal-tar fuel oils are produced in varying types
